THE PHYSICIAN AS PHYSIOLOGIST.

A Contribution to the Study of the Blood and Blood-pressure. By George Oliver, M.D. London, F.R.C.P. Pp. xii + 276. (London: H. K. Lewis, 1901.) Price 7*s.* 6*d.*

IT is to be feared that most medical men who are engaged in the active practice of their profession have little idea of making a practical application of the knowledge of physiology which they were at so great pains to acquire during the student period of their career. There are, however, many exceptions, and prominent amongst them the author of the little work which it is our present purpose to notice. Dr. George Oliver is fortunate in that his sphere of practice has given him leisure during several months in each year to study at length such physiological problems as have appeared to him to bear more directly upon the affections which he has been mainly called upon to treat, and the result of his studies has been a not immaterial addition to our knowledge of the physiology of the circulation and of the blood. Such addition has been obtained largely by the devising of methods which have more immediate applicability to the human subject than those which are in common use in the physiological laboratory. Not that Dr. Oliver has neglected the more strictly scientific study of physiological questions; as is evidenced by his well-known investigations into the functions of the ductless glands. But in the book before us the methods which are described are solely those which, whilst maintaining a high standard of scientific value, have a direct clinical application, and the observations which are given are the results of such application in the normal and occasionally in the abnormal subject, extending over a period of some ten years.

The first method which is described is that for determining the amount of colouring matter (hæmoglobin) in a sample of blood. For this purpose two chief procedures have come into use clinically. The principle of the one is that of taking a standard solution of hæmoglobin of known dilution and diluting the sample of blood to be tested until its tint is similar to that of the standard (method of Hoppe-Seyler, modified by Gowers by the use of a picrocarmin gelatin, standardised to a known strength of hæmoglobin solution). The other proceeds on the principle of diluting the sample of blood to a constant extent and comparing it with glass tinted to resemble solutions of hæmoglobin of known degrees of dilution (method of Fleischl). In practice this method is the more simple and accurate, and has been adopted by Dr. Oliver, who has, however, for adequate reasons discarded the use of a coloured glass wedge which is the characteristic of Fleischl's hæmometer, and has adopted, instead, a series of coloured glass discs which represent gradations (percentages) in the amount of hæmoglobin of blood as compared with the normal. One of the most important reasons for this modification of the method is of great scientific interest; for it was found by Dr. Oliver, when making observations with Lovibond's tintometer on the mixture of colours required to reproduce exactly the tint of solutions of hæmoglobin of different strengths, that it is not possible to take a glass of a tint the same as that of a fairly strong solution of hæmoglobin and, merely by decreasing its thickness, to imitate the colour of a very weak solution, but that it is necessary, also, to alter the tone of colour with the change in strength of the solution, *e.g.* for comparison with weaker solutions of hæmoglobin it is necessary to add more yellow to the tint of the glass standards which are used for comparison with stronger solutions. The second method described is one for rapidly computing the number of coloured corpuscles in a given sample of blood. The older method depends upon the actual counting of the number in a measured quantity of blood diluted to a known amount with an isotonic solution of salts; indeed, all methods of computation must be standardised by this one. But such computation is laborious and takes some 15 minutes at the very least, whereas by the procedure devised by Dr. Oliver a satisfactory result can be obtained in less than 5 minutes. The method takes advantage of the fact that the coloured corpuscles of the blood impart opacity to any fluid in which they are suspended in sufficient number, and with normal blood taken as the standard a less or greater percentage of corpuscles than the normal can be at once arrived at with considerable accuracy by determining at what dilution the flame of a candle can be seen through the mixture. By the employment of this method Dr. Oliver has made many determinations of the percentage (as compared with normal) of corpuscles in blood taken under different conditions both in health and disease, the chief of these varying conditions being those relating to time of day, rest and exercise, digestion, temperature and altitude. It is known that the number of red corpuscles per cubic millimetre may rise from 4,500,000 at sea-level to 7,000,000 or 8,000,000 at elevations of from 6000 to 14,000 feet above sea-level. This has been determined by Viault on the Cordilleras and by Egger and others on the Alps, and is confirmed by the author, who finds that the increase is apparent within 24 hours and attains its maximum within the first week. It is, however, not as great as had been supposed; part of the former results depending upon an inaccuracy (at low barometric pressures) in the instrument usually employed for enumeration, an inaccuracy not shared by the cytometer employed in these investigations. The description of these two methods and their results occupies nearly one half of the book, the other half being taken up by a description of methods for investigating the condition of the blood-vessels.

Of these the first is one for determining the average blood-pressure in the arteries. It is based upon the ascertained fact that any instrument which is used to observe the arterial pulse by external application gives the largest indications of pressure variations when the force with which it is itself pressing upon the artery is equivalent to the average blood-pressure within the vessel. This principle has already been employed for gauging the blood-pressure in man by Mosso and others, but the instrument which has been contrived by Dr. Oliver for the purpose, and which he called a "hæmodynamometer," is both more sensitive and more easy of application than most others which have been devised, the pressure being applied to a spring through an india-rubber bag or pad filled with fluid, and the indications being directly read off upon a dial (as in Hill and Barnard's original sphygmoscope). An even more ingenious instrument is the "arteriometer," which directly and with great accuracy measures the calibre of an artery, such as the radial, through all the tissues which cover it. Dr. Oliver has, with the aid of these instruments, recorded a very large number of observations upon the effects upon blood-pressure and upon the arteries of varying physiological conditions such as posture, exercise, emotions, rest and sleep, fatigue, food and digestion, temperature and climate; for the details of these and for many other observations on the effects upon the circulatory system of baths, massage and various other forms of treatment the interested reader is referred to the account which the author has himself given. The book furnishes an excellent illustration of what can be done by the scientific physician for the advancement of physiological knowledge, and its perusal will repay, not only the clinician for whom it is primarily intended, but also the physiologist who desires to compare the results which he obtains by experiments upon animals with those which can be obtained by experiments upon man.

E. A. S.

A GERMAN NATURALIST IN THE WEST INDIES AND AMERICA.

Von den Antillen zum Fernen Westen; Reiseskizzen eines Naturforschers. By F. Doflein. Pp. iv + 180. Illustrated. (Jena: G. Fischer, 1900.) Price M. 6.50.

WHILE containing little or nothing in the way of absolute novelty, this narrative of the travels of a German naturalist in the West Indies, Mexico, California, and the far North-West of America is a pleasantly written and charmingly illustrated volume which can scarcely fail to interest and attract a large number of his fellow-countrymen. According to the author, German travellers but seldom visit the countries through which he passed, so that the greater part of what he has to tell will be new to the majority of his readers. With the exception of two, the originals of the photographic illustrations, which add so much to the attractiveness of the volume, were taken by the author himself; and the exquisite manner in which these photographs have been reproduced reflects the highest credit on the firm to whom the task was entrusted.

The first part of the book, which is divided into seven chapters, is devoted to the West Indies, where Martinique was the first island visited. Here the author was much interested in the botanical gardens, where he was struck by the richness of the vegetation, and especially by the luxuriance of the lianas. Several charming views in the island are given.

The author's next point was Barbadoes, where he left the great ocean steamer to take passage in a smaller vessel for a cruise among the lovely isles of the Lesser Antilles group. After devoting several chapters to his experiences among these, the narrator discusses in the sixth the racial problems presented by the West Indies, illustrating a few characteristic types. In Chapter vii. he treats of the fauna of the Lesser Antilles, dwelling on the close connection existing between the animals of that group and those of Venezuela, Colombia and Central America, and giving good pictures of a few of the more remarkable forms, among them the dreaded *fer-de-lance* snake. A section of this chapter describes in some detail the coast fauna of Martinique, a striking feature of this part being the photograph of a tropic-bird in flight.

The remaining nine chapters, forming the second half of the volume, describe the continental portion of the author's tour, and are at least as full of interest as their predecessors. In the first of these chapters (viii.) we have an instructive sketch of the ancient buildings and weapons of Mexico, which the author calls the Pompeii of America. In addition to a view of the celebrated temple of the sun and photographs of stone weapons, the author gives a plate of human and animal clay masks collected by himself at Teotihuacan. In Chapter ix. we have a description of a traverse of the great desert tract of Mexico, illustrated by an excellent photograph of giant cactuses; while, in striking contrast to this, the reader, in Chapter x., is introduced to the glories of a summer's day in California. Following the latter is a description of a Chinese settlement in the same country, where the photograph of "Chinatown" will not fail to impress the reader with the importance assumed by the Mongolian element in this part of America. Nor is zoology by any means neglected, Chapter xii. being devoted to an account of the Californian marine fauna, illustrated with a photograph of one of the remarkable Pacific hag-fishes of the genus Bdellostoma, and a second of the Californian medusa-starfish. Lovers of forest scenery will be enchanted with the beautiful photograph of a Sequoia-forest in California, which forms the most striking feature in the thirteeenth chapter; this chapter dealing, not only with the primeval forests of the district, but likewise with the timber-felling industry.

In his concluding chapter, Dr. Doflein presents his readers with a capital account of the Yellowstone Park and its animal wonders, illustrating his description with an excellent photograph of a family party of black bears in their native wilds. The photograph of bisons is, however, by no means so successful as it might be, being, for one thing, on much too small a scale. Still more unsatisfactory is the one on page 175 lettered "Die Amerikanische Gemse (Weibchen)," which is intended to portray the female of the prongbuck. If we are not mistaken, the animal in the foreground is a wapiti hind, while the one in the middle distance might be anything.

To any English reader desirous of keeping up his German by the perusal of a pleasantly written narrative of travel, Dr. Doflein's work may be commended; to his own countrymen it will commend itself. R. L.

A BIBLICAL ENCYCLOPÆDIA.

Encyclopaedia Biblica, Critical Dictionary of the Literary, Political and Religious History, the Archaeology, Geography and Natural History of the Bible. Edited by Prof. T. K. Cheyne and Dr. J. Sutherland Black. Vol. ii. E—K. (A. and C. Black, 1901.) Price 20*s*. net.

A WORK like this demands a critic whose forte is omniscience, for the articles are written by men who can speak as authorities, and necessarily enter into questions of theology, a province of human thought with which science is only indirectly concerned. This alone makes it difficult to give any notice of the book in a publication strictly scientific. To read through a volume of 1544 closely printed columns of small type would be a herculean task which we do not pretend to have attempted. We have not perused more than a few of the salient articles in the present volume, which, as it contains the letters from E to K, happens to include a large number of exceptional interest. If we remember that even the letter J covers names such as James, Jasher, Jeremiah, Jerusalem, Jesus, Job, John, Jordan, Joshua, Joseph, Judah and Judges we realise the significance of many articles. These seem to be summaries of everything important that has been written on the subject. Indeed, sometimes the variety is a little bewildering to the ordinary reader, who, however, cannot complain of a stinted choice, though the writers generally favour views distinctly progressive. One or two slips, notwithstanding the care with which, obviously, the work has been done, have caught our eye, such as the statement that the vicinity of Jerusalem consists of strata of the Eocene and *Chalk* formations—where Cretaceous should have been written, as the limestone is not the variety designated chalk; or the obvious clerical error that Esdraelon lies 250 feet *below* the sea-level, which would make it difficult for the river Kishon to reach the Mediterranean. But the topographical articles, which of course have to be largely dealt with from the historical point of view, are generally excellent. For instance, the article "Geography" gives a most interesting account of what was known about that subject by the Old Testament writers. Formerly, no doubt, when the relations of theology and science were ill-understood, questions of Hebrew cosmogony and ethnology were more important than they now are; still there is an antiquarian interest, when the date of a document can be approximately determined, to see how much or how little the Hebrews had ascertained about the rest of the world. Evidently the knowledge of the Old Testament writers hardly extended eastward beyond Persia, or northward so far as the Caucasus, or southward beyond Ethiopia on the African continent, or westward of Greece, excepting Tartessus in Spain or possibly either Sicily or Carthage. If they had any notions of regions lying beyond those limits, such as India or China, these must have been of the vaguest, unless we locate Ophir in Mashonaland, to which identification, however, as we infer from the article on gold, the editor does not incline. The books of the Old Testament cover a long time, and knowledge grew; but we may safely assume that the writer of the ethnographical notices in Genesis x., whatever be their date, either did not know of, or deliberately excluded, the Black and the Yellow races. Probably, indeed, until about the tenth century before our era, the Hebrews had only a very limited knowledge of geography. The article on Egypt is full of information and has been brought down as nearly as possible to date. It is accompanied by three very useful little maps; one, a physical map of the Nile valley, north of Khartoum, another, on a smaller scale, of the Nile and the Euphrates, and a third showing the broader features of the geology. This brings out very clearly the close connection between the Sinaitic peninsula and the mountain region between the river and the Red Sea, and contains much information in a very small space.

A comparison of the historical part of this article with that in Smith's "Dictionary of the Bible," published in 1860, indicates, better than anything, how enormously our knowledge has been increased during recent years. The same is true in regard to the articles on the topography of Jerusalem. No doubt the one in the older work was below the general level, for the editor, owing to some strange infatuation, had accepted as established facts the absurd fancies of the late Mr. James Fergusson. These are properly ignored in the work before us, which treats this difficult and thorny subject in a fair and scholarly fashion. The author may sometimes incline to one view, the reader to another, but evidence is not perverted as it was in the older work. Personally, for instance, we do not believe the Ophel Hill to have been the site of the City of David. The passages supposed to be favourable to this identification are not, in our opinion, of much weight, and the distance of Jebus from any known spring is a difficulty which attaches to many hill forts. Some in our own country could not have endured a close siege for a few days without storage of water, and cisterns were familiar things at Jerusalem.

The western hill, like another Gergovia, is a natural site for a hill fort, while the descending ridge of Ophel, so far as we can infer from our studies of such structures, is exactly the position which their builders would have avoided. Such articles as "Gospels" and "Jesus" introduce us to questions of a character and a theological import which we must not discuss in these columns. Suffice it to say that, while indicating a certain amount of reaction from the extreme vagaries of representatives of the so-called "higher criticism," they express, as a rule, eminently "progressive" views. Some, indeed, are so very advanced that they could not, so far as we can see, be covered by the most liberal interpretation of the Nicene creed. Persons, however, who view with anxiety these removals of ancient landmarks may comfort themselves by observing how many idols of the cave have been set up by one confident discoverer only to be trampled under foot by the next comer. Indeed, on reading some of these efforts of the higher criticism we cannot help being reminded of the famous Historic Doubts, and think that by using similar methods we could prove William the Conqueror to be a person almost mythical and the Battle of Hastings mainly a legend. T. G. B.

OUR BOOK SHELF.

Plato's Staat. F. Schleiermacher. Zweite Auflage. C. Th. Siegert. (1901.) Mk. 3.

John Locke's Versuch über den Menschlichen Verstand. Zweiter Band. Zweite Auflage. C. Th. Siegert. (1901.) Mk. 3.

Berkeley's Abhandlung über die Prinzipien der Menschlichen Erkenntnis. Dr. F. Ueberweg. Dritte Auflage. (1900.) Mk. 2.

Berkeley's Drei Dialoge zwischen Hylas und Philonous. Dr. R. Richter. (Leipzig: Dürr'schen Buchhandlung, 1901.) Mk. 2.

THERE is in Germany a widespread appetite for metaphysics. Earlier there than elsewhere scholars and philosophers of an order not far removed from the highest came to recognise that work bestowed on the translation and elucidation of foreign masterpieces in philosophy was the best of trainings in exact thinking and expression. The zeal of von Kirchmann for his educational ideal was untiring, and his industry was appalling. In the result, the *Philosophische Bibliothek* has succeeded in combining low cost and high achievement. It is the more to be regretted that its volumes so often come to pieces in the hand.

Schleiermacher's translation of "Plato's Republic," with von Kirchmann's sporadic notes, "needs no bush." It will not, of course, be much used in England after the labours of Davies and Vaughan and Dr. Bosanquet. It has undergone some revision, but still scorns Greek accents, while its use of breathings is haphazard. Similarly, von Kirchmann's translation of "Locke's Essay" has undergone revision before reissue. Something of the effect of Locke's style vanishes in the translation, but the substance is there. It is only the separate volume of notes which is likely to interest the English public, and that not greatly. Ueberweg's excellent version of the masterwork of Berkeley's earlier idealism has passed into a third edition, advisedly without revision. Its incisive notes possess some value even for those who have studied their Berkeley with the aids supplied by Prof. Campbell Fraser. It has a worthy successor in Dr. Raoul Richter's translation of "Berkeley's Three Dialogues between Hylas and Philonous." If we have not been singularly unfortunate—or fortunate—in our sampling, Dr. Richter has succeeded as well as the translator of Berkeley could hope to succeed. He adds a straightforward introduction and some luminous notes chiefly on the usage of technical terms. The new series is, to our thinking, superior in form, printing and, above all, in stitching, to the old. The student, for whom the reading of Kant or Hegel in the original is only a hope of the distant future, might be worse advised than to take Dr. Richter's version of the dialogues and ground himself in German philosophical terminology by reading it along with the brilliant original. An English translation of a German "minor masterpiece" at once as excellent as this and as cheap is still to seek.

H. W. B.

The Fishes of North and Middle America; a Descriptive Catalogue of the Species of Fish-like Vertebrates, found in the Waters of North America, North of the Isthmus of Panama. By David Starr Jordan and Barton Warren Evermann. Part iv. Pp. ci + 3137–3313; plates I–CCCXCII. (Washington: U. S. National Museum, 1900.)

THE present part concludes this important work, of which we have given a full notice in vol. lxi of NATURE, p. 362. It commences with a systematic arrangement of the fishes described, which serves not only as a table of contents for all the four parts, but also as an exhibition of the views of the authors as to the genetic relations of American fishes. From it it will be seen that the fish-fauna of North and Middle America, as now understood and as stated by the authors, embraces 3 classes, 30 orders, 225 families, 1113 genera, 325 subgenera, 3263 species and 133 subspecies. "Additional Addenda" follow and occupy some 60 pages; they comprise a number of new genera and species described since the publication of part iii., the majority being the result of investigations made by Dr. Jordan in Mexico, and by Dr. Evermann in Porto Rico. Other additions or corrections regarding nomenclature, relations and distribution of previously known species, are duly attended to.

The bulk of the volume is devoted to the illustrations. In this series are represented about 958 types of fishes, thus, so far as numbers are concerned, surpassing even Cuvier and Valenciennes' "Histoire naturelle des Poissons," in which only about 700 species are figured. With few exceptions, the figures are original, and were drawn for the present work from specimens preserved in American collections, and by means of photography reproduced to a uniform size, the width of an octavo page. As the work has been published by the Smithsonian Institution with the view of bringing it within the reach of the people, no highly artistic and, therefore, expensive finish of the illustrations has been attempted; but they have not lost in accuracy thereby, and will fully answer the purpose of assisting the student of ichthyology in his initial studies, or the layman who seeks for occasional information. They show well the general appearance of the fish, the structure of fins and the arrangement of scales; but scarcely any additional details are given to illustrate the characters on which the numerous genera and species distinguished or adopted by the authors are based.

The illustrations are preceded by an explanatory list, in which the names of the artists, the numbers of the original specimens in the United States National Museum, or other sources whence the drawings were derived, are carefully noted. In fact, no pains have been spared by the authors to render their work instructive and handy for reference and ready use.

Already in our first notice we have testified to the high merits of the work; it renders the rich American fish-fauna more accessible than ever before to scientific ichthyologists throughout the world, and cannot fail to give a powerful impetus to the study of fishes in the authors' own country. A. G.

Die wissenschaftlichen Grundlagen der analytischen Chemie elementar dargestellt. Von W. Ostwald. Dritte Auflage. Pp. xi+221. (Leipzig: Engelmann, 1901.) Price M. 7.

THE services that Prof. Ostwald has rendered to physical science during the last quarter of a century are so numerous and so valuable that his writings cannot fail to exert considerable influence. In working out and extending the theories of van 't Hoff and Arrhenius he played a leading part in laying the foundations of physical chemistry; and in applying these principles to the consideration of the problems of analytical chemistry, he has effected a complete revolution in the methods of approaching that subject. In 1894 he published the first edition of the "Wissenschaftliche Grundlagen," and thus furnished us with scientific explanations of much that up till that time had been little more than mere empiricism; analytical processes were interpreted by him in the light of the theory of solutions and the ionic hypothesis, and thus new life was infused into a branch of science that had become almost moribund.

It is gratifying to think that Prof. Ostwald's efforts have been appreciated; and the fact that a third edition of this striking work has been called for is sufficient evidence of its success. The new ideas are beginning to take a firm root, and are already finding their way into the latest text-books on the subject.

It is to be hoped that teachers of practical chemistry will study the pages of this last edition of the "Grundlagen der analytischen Chemie," and arrange their methods of instruction on the new lines it suggests. With this end in view Prof. Ostwald has added a chapter containing descriptions of a number of experiments illustrating some of the more important principles on which analytical chemistry is based.

In conclusion, we would draw attention to the closing words in which the author advocates the use of as simple apparatus as possible, that the attention of the student may be concentrated on the chief features of the experiment. Coming from so brilliant an experimenter and so popular a teacher, the advice is worthy of special emphasis.

An Introduction to Modern Scientific Chemistry. By Dr. Lassar-Cohn. Translated by M. M. Pattison Muir, M.A. Pp. viii + 348. (London: H. Grevel and Co.)

THE German original of this book has already been noticed in these columns (vol. lxi. p. 51, 1899). It has been translated into smooth English by Mr. Pattison Muir, and it may be cordially recommended as a clear exposition of the leading facts and principles of chemistry, well adapted to the class of readers for whom it was written, namely, University extension students and general readers. It must be borne in mind that the book is not intended for those who are able to study chemistry with their own *hands.* The fifty-eight illustrations in the book are its worst feature, but they are by the author, and no doubt the translator had no choice but to reproduce them. A. S.

First Aid to the Injured. By H. Drinkwater. Pp. 104. (London: J. M. Dent and Co.; no date.) Price, 1*s.* net.

THE number and excellency of the illustrations are special features of this little book, and increase its interest and clearness, doing away also with the need of lengthy explanations. The proportion between the theoretical and practical parts is well maintained. The anatomical details are not by any means unduly prominent, but are only introduced in so far as they are necessary to enable the practical directions to be intelligently followed. The book can be strongly recommended as a clear and trustworthy instruction in "first aid."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Solution of Cubic and Biquadratic Equations.

THE historical note in your last number by Sig. Vacca regarding the graphical solution of a cubic, given by Mr. T. Hayashi, reminds me that I had intended, when Mr. G. B. Matthews published his suggestion for the graphical solution of a biquadratic by means of two parabolas (NATURE, Nov. 16, 1899), to point out that he too had been anticipated, as will be seen by referring to a paper by Mr. R. E. Allardice in the *Proceedings* of the Edinburgh Mathematical Society (April 7, 1890), where it is shown that, with the exception of the case where the roots of the biquadratic are equal in pairs, the real roots of the general biquadratic can be found graphically by means of two equal parabolas having their axes at right angles, the one fixed and the other movable; and also that every cubic can be reduced to the form $y^3 \pm y + r = 0$; and then solved graphically by means of the fixed curve $y = x^3$ and the movable straight line $x \pm y = r$.

I may take this opportunity of calling the attention of elementary teachers to the fact, also dwelt upon in Mr. Allardice's paper, that the most convenient method of discussing the algebraic solution of the general biquadratic, and of testing whether any particular biquadratic is soluble by means of quadratics or not, depends on the familiar theorem that $ax^2 + 2hxy + by^2 + 2gx + 2fy + c$ is decomposable into linear factors if $abc + 2fgh - af^2 - bg^2 - ch^2 = 0$, and not unless. Along with the biquadratic $x^4 + px^3 + qx^2 + rx + s = 0$ (1) consider the equation $x^2 - y = 0$ (2). By interequational transformation it is obvious that the system (1), (2) is equivalent to the system composed of (2) and $qx^2 + pxy + y^2 + rx + s = 0$ (3). Again, the system (2), (3) is equivalent to the system composed of (2) and $(q - \lambda)x^2 + pxy + y^2 + rx + \lambda y + s = 0$ (4), where λ is a constant at our disposal. If λ be so chosen that the left hand side of (4) breaks up into linear factors; that is, if λ be a root of the cubic

$$\lambda^3 - q\lambda^2 + (pr - 4s)\lambda + 4qs - r^2 - p^2 s = 0 \qquad (5),$$

then the system (2), (4) will be equivalent to two systems $y + \mu x + \nu = 0$, $y = x^2$, and $y + \rho x + \sigma = 0$, $y = x^2$. In other words, the four roots of (1) are the roots of the two quadratics $x^2 + \mu x + \nu = 0$, $x^2 + \rho x + \sigma = 0$.

The cubic (5) is not in general soluble by means of quadratics without the adjunction of a cube root: hence the solution of a biquadratic in general depends on the solution of a cubic and two quadratics.

The necessary and sufficient condition that the cubic be soluble by means of quadratics is that it have a commensurable root, which, if it exist, can be readily found by finding an integral root of another cubic of the form $x^3 + ax^2 + bx + c$, where a, b, c are all integral. The determination of μ, ν, ρ, σ then requires, in addition to rational operations with p, q, r, s, λ, merely the extraction of a square root.

To the tyro who is familiar with the elements of the coordinate geometry of the conic sections the rationale of the above process can be made evident by the consideration of the two line-pairs which contain the four points of intersection of two conics. It may be noted that, instead of the parabola $y = x^2$, we may use the rectangular hyperbola $xy = 1$, the only difference being that we are led to a different cubic resolvent.

Considering the space usually given in English text-books of algebra to the discussion of equations which are soluble by means of quadratics, it is strange that few, if any, of their authors emphasise the fundamental fact that the reduction of a biquadratic which is soluble by means of quadratics can be effected by finding the rational root of a cubic equation. I fear that I too must plead guilty to this omission, which among other things I propose to make good in the next edition of vol. i. of my "Algebra." G. CHRYSTAL.

Edinburgh, April 26.

Electro-Chemistry.

ALLOW me to point out an omission unnoticed by your reviewer of Mr. Bertram Blount's book on practical electro-chemistry (p. 582). Mr. Blount refers to the electrolysis of gold ore as a failure (Haycraft's method).

The omission is probably due to the fact that the process in question (Riecken's) has not been worked on a large scale except during the last three or four months, though the patent is three years old. Its efficacy depends essentially on securing a clean mercury kathode in the form of a thin stream of mercury flowing over a nearly vertical copper plate.

The liquid containing the pulverised ore is a continually agitated solution of cyanide and the anode is of iron, as the electro-motive force, one and a half volts, liberates nothing more corrosive than cyanogen. The particles of gold are doubtless cleansed of the obstructing sulphide and tellurous films by the convection currents of ionised cyanogen and also, in a more direct way, by the current as it passes through each particle, making in effect one side of it a kathode and the other an anode, just as is seen if we suspend a piece of metal in an electrolyte between the electrodes and unconnected with either.

This simple invention may revolutionise the treatment of refractory ores, yet apparently the inventor could get no hearing for three years till, at his own cost, he erected apparatus on a working scale in West Australia. The facts are valuable as showing how great an interval separates German intelligence from British engineering practice.

Intelligence of any kind, foreign or native, must indeed have been wanting when huge works, regardless of cost, were erected in presence of the published electrolytic method which could have been effectually tested in a single vat.

JOHN HILL TWIGG.

IF, as your correspondent, Mr. Twigg, says, Riecken's electrolytic process has only been worked on a large scale during the last three or four months, it is not unnatural that Mr. Blount has omitted to describe it. In most cases Mr. Blount has endeavoured to describe processes which are of proved utility, and therefore it was hardly necessary to draw attention to the omission. Further, the number of patents on the subject of electrolytic gold refining is very large, so that it would be manifestly impossible to describe them all. Riecken's process is a very neat one, and should any of the readers of NATURE be interested in the subject, an excellent description is to be found in the "Jahrbuch der Electrochemie" (vol. v. p. 380).

F. MOLLWO PERKIN.

Unusual Agitation of the Sea.

ON Wednesday, April 24, on going to the edge of the cliff above Alum Chine, Bournemouth, at 7.50 a.m., I was struck by the appearance of a succession of waves, resembling a slight ground swell, reaching the shore from an otherwise calm sea, there being no wind. The character of the waves was rather peculiar, and I then saw that every now and then, at intervals of about two or three minutes, much larger waves came in, and instead of breaking abruptly, extended quietly up the sandy beach to a greater height than was expected from their apparent elevation. I mentioned the phenomenon on reaching the house, and on the suggestion that the waves were the result of a distant storm, could not see that they might be so accounted for. Between 12 and 1 p.m. I again watched the undulations, and roughly measured the length on the beach by which the larger waves extended further than those of ordinary size. This was about 22 feet. The larger waves were less frequent than in the morning. Later in the afternoon, soon after 3 o'clock, some of my family were caught by the exceptionally large undulations, which rose surprisingly high upon the slightly sloping sand.

I have not heard whether any remarkable disturbance has been recorded by the seismometer, but I see in the *Daily Mail* and *Daily Express* of April 25 and 26 telegraphic reports of earthquakes in Italy, Portugal and Guernsey on April 24.

ROLLO RUSSELL.

RECENT DEVELOPMENTS IN ELECTRIC SIGNALLING.

IT is thirteen years since Hertz carried out the brilliant series of experiments which, apart from their great theoretical value, had the important effect of laying the foundation of modern systems of wireless telegraphy. Three years later we find the *Electrician* making the suggestion that the discoveries of Hertz might be utilised for signalling to lightships, and five years later still, in 1896, Signor Marconi brought over to England the first practical wireless telegraphic apparatus and awakened public interest by the remarkably successful experiments which he carried out on Salisbury Plain and across the Bristol Channel. For a time the technical and lay Press was full of wireless telegraphy; great prospects were predicted for it; communication with lightships and lighthouses was the least of the feats it would accomplish; telegraphy at sea was to become as common as on land; some even went so far as to say that wires and cables of all sorts for telegraphic purposes were to become a thing of the past. But these revolutionary changes, if they are ever to be made, did not come with the rapidity which many apparently expected. It was soon recognised that we needed to know a great deal more about the subject before Hertz waves were to be even a trustworthy servant to the telegraphist, and even now we can scarcely call wireless telegraphy much more than experiment. But we have now more definite grounds for feeling sure of its ultimate success, and we can predict for it a useful future with much more surety and reason than was done in the first outburst of enthusiasm that followed Mr. Marconi's experiments.

The patient and persevering experimenting of the past five years has led to the gradual surmounting of many of the difficulties which at first beset wireless telegraphy, and Mr. Marconi, Prof. Slaby and the other pioneers who have thrown themselves with vigour into its development have met with a success which, if not complete, is yet very promising. It is not the greatly increased distance over which it has become possible to signal, an increase from a few miles in 1896 to more than 200 in 1901, that marks the most important development that has occurred. The greatest achievement is the successful solution of the problem of tuning. It was early seen that before wireless telegraphy could have at all an extended utility it would be necessary to find some means of confining each message to its correct destination and of preventing each receiving apparatus from responding to Hertz waves sent out from any transmitter in its neighbourhood. It seems that now almost all experimenters have overcome this difficulty, at any rate to a certain extent.

The improvement in distance over which it is possible to signal has been very marked. The empirical law put forward by Mr. Marconi that, other things being equal, the distance over which signalling would be possible was proportional to the product of the heights of the masts at the two ends seems to be fairly well established as a working rule. But the improvements in transmitting and receiving apparatus have been so great that it is now possible to signal over much greater distances with the same heights of masts than was the case in 1898. For example, in 1898 Mr. Marconi was only able to cover 15 miles with vertical wires 120 ft. high, whereas to-day, according to the recent announcement made by Prof. Fleming, a distance of 200 miles from the Lizard to St. Catherine's, Isle of Wight, has been signalled over with masts only 160 ft. high. Mr. Marconi certainly holds the record for long distance work. The example just quoted refers to signalling across sea; across land such great distances have not been attained, but here again we think the credit of having signalled over the greatest distance must be given to Mr. Marconi, who established in 1899 communication between Dovercourt and Chelmsford, a distance of more than 40 miles.

These long distances have been attained by Mr. Marconi partly by the use of a specially constructed transformer in the receiving circuit. Instead of connecting the vertical receiving wire in series with the coherer it is connected in series with the primary of this transformer, the secondary of which is in series with a condenser and the coherer. By this means the voltage of the received oscillations is increased, and the resistance of the coherer more easily broken down. A somewhat analogous arrangement is used by Prof. Braun, to whose work allusion has already been made in NATURE,[1] in the transmitting circuit, the oscillations in the vertical wire being set up by induction and not by directly including the spark gap between the vertical wire and earth. The results that have been obtained by Prof. Braun are not, however, nearly so good as Mr. Marconi's latest work.

So far as tuning is concerned, Mr. Marconi appears to have successfully got over this difficulty. Prof. Fleming, in the lecture above referred to, stated that the communication between the Lizard and St. Catherine's was multiplex, it being possible to receive two or more messages at once at each place. Mr. Marconi himself, in an interview with an American contemporary, said that with his improved apparatus he could send or receive 2, 10 or 50 messages at the same time, without any interference whatever. Particulars as to the method have not, however, been published as yet, but it is to be hoped that the details of the system will be explained by Mr. Marconi at his forthcoming lecture at the Society of Arts.

In Germany the subject of wireless telegraphy has been tackled principally by Prof. Slaby and Count Arco, who took up the subject in order to find a system for the German Navy, to replace that of Mr. Marconi, the Marconi Company charging, it was said, prices prohibitive to any but the English Navy. Although the results, so far as distance is concerned, which Prof. Slaby has obtained are not very great, the system that he has developed is one of great interest and seems to be founded on sound scientific principles. Prof. Slaby has aimed throughout at getting rid of interference by producing only oscillations of a definite wave-length and tuning the receiver only to respond to these particular waves. In order to produce the oscillations, the transmitting circuit is arranged as shown in Fig. 1. An earthed loop of wire, ACDE, is used, instead of the single insulated vertical wire usually employed, in one arm of the loop there being a spark gap, AB, and a condenser, K. The ends C and D of the vertical wires are joined by a coil of wire as shown. In charging the condenser the whole loop is used, but in discharging it is only the arm ABC which is utilised, the coil of wire CD preventing the oscillations passing into the remainder of the circuit. Upon the length of the wire KC and the capacity of the condenser K the wave-length of the oscillations depends, and from their known values it can be calculated.

Theoretical considerations showed Prof. Slaby that the free ends of both the transmitting and receiving wires, *i.e.* the ends C and E (Fig. 2), are potential loops, and that the earthed ends B and D are potential nodes. If, now, to the receiving wire DE a second wire, DF, equal in length to CD, is connected, there will be a potential loop at F. At E and F, therefore, the potential will vary over a much greater range than at D. If at F a further length of wire, J, is attached, such that its length is half a wave-length, then there will be established between F and the free end, G, of the coil J a difference of phase of 180°. At both points there will be potential loops, but when the potential F has a maximum value in one direction that at G will have a maximum value in the opposite direction, and the potential difference between F and G will be double that between F and earth. By connecting the coherer between F and G it can thus be made to respond to received oscillations much feebler than those which would be required to work it if it were connected, as is usual, between D and earth. As an additional advantage, the earth connection at D can be removed, and the whole receiving apparatus thus rendered earth free.

Experiments have been made from time to time to devise a suitable repeater for use with wireless telegraphy, and the results of some work which has been done by M. Guarini on this subject were recently published in the *Electrician*.[1] M. Guarini established stations at Brussels, Malines and Antwerp; messages were successfully transmitted between Brussels and Malines and also between Malines and Antwerp, and a repeater was then set up at Malines with the object of automatically transmitting the messages received from Antwerp to Brussels. The experiments were not, however, very successful, as the repeater did not always transmit the signals, and it was found, consequently, impossible to send any actual messages. A trustworthy repeater for wireless telegraphy would be very useful, but it is scarcely necessary to point out that it must be absolutely trustworthy, as if a man has to be on the spot to keep it up to its work he may as well be employed in retransmitting the messages.

In the meantime the wire-using telegraphists have been by no means panic stricken by the achievements of their wireless competitors, and some very notable developments have taken place during the past few years. We can only describe here a few of these; those who are more deeply interested in the subject may be referred to Mr. Gavey's paper on telegraphs and telephones at the Paris Exhibition, read recently before the Institution of Electrical Engineers,[2] in which will be found descriptions of all the more important improvements effected in the last few years. One of the most remarkable is the Pollak-Virag high-speed telegraphic system. This system attracted considerable attention both in the technical and lay Press when it was first brought forward, towards the end of 1899, on account of the extremely high speed of signalling which it was said to be possible to attain by its use. It was reported that in trials in America a speed of 60,000 words an hour had been maintained over a line which was over 1000 miles in length, and that a speed as high as 100,000 words an hour had been attained. This is a very great improvement on the 400 or 500 words a minute possible with the Wheatstone automatic or Delaney multiplex systems, which are those commonly in use in this country. These remarkable results had been achieved by the use of a telephone diaphragm as the receiving instrument, the diaphragm being deflected by the currents received through the telegraph line and a deflection in one direction corresponding to a dash and in the opposite direction to a dot. The movements of the diaphragm were recorded photographically, a small mirror being attached to the diaphragm and a ray of light being reflected from this on to a revolving drum covered with a roll of sensitised paper. The record had, of course, to be subsequently developed in the ordinary manner.

Since its first introduction the system has undergone considerable development, a very ingenious modification

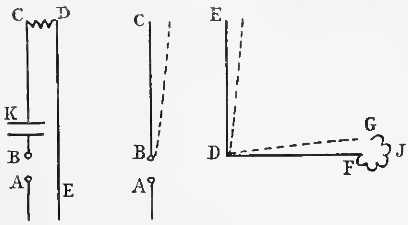

FIG. 1. FIG. 2.

[1] NATURE, 1901, vol. lxiii. pp. 403 and 474.

[1] The *Electrician*, March 22, 1901, vol. xlvi. p. 819.
[2] *Journal* of the Institution of Electrical Engineers, 1901, vol. xxx. p. 73.

having been introduced by means of which the recorded message is written in ordinary Latin characters and can consequently be read by any one. In order to do this it is necessary to give the mirror on the receiving instrument a horizontal as well as a vertical motion, and for this purpose two circuits are needed and two telephone diaphragms, one giving the mirror vertical movements and the other horizontal. A single metallic loop is employed, one telephone being put in the loop and the other between the loop and earth. Horizontal movements of the mirror, to right and to left, are produced by currents passing round the loop in one direction or the other respectively, and vertical movements by currents passing from the loop to earth; in this second case an upward movement is produced by a current in one direction and a downward movement by a current in the opposite direction, and also a downward movement of double the distance by a current at double the normal voltage.

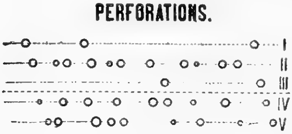

FIG. 3.

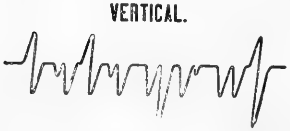

FIG. 4.

FIG. 5.

FIG. 6

The line currents are sent by means of perforated strips of paper much in the same way as in the Wheatstone transmitter, but five strips are used, three to give the vertical components and two for the horizontal. These strips are shown in Fig. 3; the rows marked i, ii and iii give the vertical components, the first row giving the tall letters and the third the deflections of double amplitude for the letters with tails; rows iv and v give the horizontal components. Deflections of a fraction of the normal amplitude are given by contacts lasting a shorter time by means of the small perforations as seen in rows ii, iv and v. The perforations are so arranged that the combination of the vertical and horizontal movements of the mirror (as seen in Figs. 4 and 5 respectively) gives the Latin characters (Fig. 6), and all the perforations for one letter are punched at the same time by means of a special machine of the typewriting kind. To obviate the difficulty of having to use a rapidly moving narrow strip of sensitised paper to receive the photographic record, as in a tape machine, a very neat device is employed. The source of light is the filament of an incandescent lamp, which is surrounded by an opaque cylinder in which a helical slit is cut. This cylinder is revolved, and as it turns the part of the filament acting as a source of light moves from left to right as the slit uncovers in succession the various portions of the filament; at the same time, the spot of light reflected on to the recording paper, which is a broad band of sensitised paper, will also move from left to right, thus writing a complete line on the paper; at the end of a complete revolution the spot will return again to the left-hand side of the paper band and will proceed to write a new line, this new line being brought under the other by a movement imparted to the band of paper. The message is thus directly obtained as an ordinary written message in lines one below the other, and the system has thus the great advantage over all Morse methods that the message has not got to be deciphered and transcribed by the receiving telegraphist. With this apparatus it is said that a speed of 1000 words a minute can be obtained.

The Pollak-Virag system, although in its most recent form it gives a record in ordinary handwriting characters, must not be confused with those systems designed to transmit the actual handwriting or drawing of the signaller. Several instruments, under the name telautographs, have from time to time been devised for this purpose, and the late Prof. Elisha Gray was, we believe, engaged on the perfecting of an invention of a telautograph at the time of his death. The attempts at solving the problem, which is, it must be confessed, a very fascinating one even though the very extensive utility of such an instrument may be questioned, have not, so far, proved very successful. Last year, however, there appeared in the technical Press descriptions of a telautograph which is the invention of Mr. Foster Ritchie, and which seems to have got over the difficulties in a very practical manner. In the Ritchie telautograph the message is written with an ordinary pencil; by means of levers attached to this pencil its movements are made to regulate the currents sent through the transmitting lines, and these currents in their turn regulate the motion of a pen at the receiving end. By an ingenious arrangement the receiving pen only makes marks on the paper when the transmitting pencil is pressed down on the writing table. The receiving pen exactly reproduces the characters written at the transmitting end, which can be written at the ordinary speed of handwriting. We hope on a later occasion to give a more detailed description of the apparatus.

We may finally describe an invention which has aroused considerable interest amongst our American cousins, namely, Dr. Pupin's system of long distance and oceanic telephony. Dr. Pupin has, we understand, disposed of his American patent rights to the American Telephone and Telegraph Company for a very large sum of money, which shows that this company have great confidence in the invention. The difficulty of carrying out successful telephony over a great length of line arises out of the fact that the line possesses both resistance and capacity; this is especially the case with submarine cables in which the capacity is large. These properties produce both attenuation and distortion of the transmitted signals, the arrival current being both very much weaker and different in character to the current sent into the cable at the transmitting end. The alteration in character is due to the fact that the more rapidly varying currents are more easily attenuated; if a varying current be sent into the cable by speaking into a telephone at the transmitting end this may be analysed, just as the sound to which it corresponds may be analysed, into a fundamental vibration and a number of higher harmonics; the higher harmonics will, after travelling along the cable to a certain distance, become so attenuated that they will be incapable of producing any effect on a receiving telephone, so that such an instrument, if placed at this point, will only be actuated by the fundamental lower harmonics, and the sound it gives out will, in consequence, be different in character from the sound originally made at the transmitting end. The effect will show itself, therefore, in defective articulation, or distortion of the sounds arising out of the distortion of the telephone currents.

It has been shown by Mr. Oliver Heaviside that there are ways in which this distortion may be prevented and a "distortionless circuit" constructed. Without entering too deeply into the subject we may point out briefly the methods by which this may be effected. Since the cable possesses capacity, the first effect of sending current into it is to charge it, and no signal can be received at the far end until the cable is partly charged, and no further signal until the charge has had time to get out. Now if the insulation resistance of the cable be diminished, the charges will more readily leak out and thus it would be possible to expedite signalling ; but at the same time the attenuation is increased, for more of the current will leak out of the cable ; the remedy is, therefore, only a partial one, for though the speed of signalling may be increased, so much current will leak out on the way that the amount arriving at the far end may be too small to work the receiving instruments. Instead of simply diminishing the insulation resistance or of distributing artificial non-inductive leaks along the cable, inductive leaks may be placed at definite points along the cable ; this method was proposed by Prof. S. P. Thompson in a paper read at the International Congress at Chicago in 1893.[1] A diagram of the cable construction suggested by Prof. Thompson is shown in Fig. 7 ; the capacity is represented as though it were not evenly distributed but

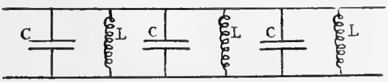

FIG. 7.

consisted of a number of condensers, C,C, connected as shunts to the cable ; the inductive leaks are represented by the coils L,L. The capacity and self-induction are therefore combined in parallel, and it is well known that they can be combined in this way so as to behave, for a definite frequency, exactly as an ohmic resistance. The capacity of a submarine cable may be partially neutralised in this way, but the remedy is only a partial one for three reasons. Firstly, the inductive leaks, to correctly neutralise the capacity, should, like the capacity itself, be evenly distributed along the cable and not distributed in jerks ; secondly, the correction will only be exact for a particular frequency ; lastly, the leakage is increased and the same defect consequently occurs as in the case considered above in which the distortion was corrected by diminishing the insulation resistance. Theoretically, therefore, the system proposed by Prof. Thompson does not offer a perfect solution or give a truly distortionless circuit ; but it would greatly diminish the distortion, though at the same time increasing the attenuation, and might therefore give a practical means of increasing the speed of signalling or even obtaining telephonic communication over the cable.

As Mr. Heaviside has shown, the only true way of obtaining a distortionless circuit—of obtaining *the* distortionless circuit, as he calls it—is to balance the effect of capacity by self-induction *distributed along* the cable in series with it and not as a leak to it. The four quantities which control the propagation of disturbances or signals along the line are its resistance, R, its external conductance, or conductivity of the insulation, K, its self-induction, L, and its capacity or "permittance," S, and the signals will be propagated without distortion if $L/R = S/K$. The equality of these two ratios may be obtained by altering any of the four variables, but practically we may consider R and S as fixed. In ordinary cables the value of the ratio L/R is very small, and that of S/K comparatively large. In order to make the two equal we may increase K, that is to say diminish the insulation resistance, but this, as we have seen, leads to excessive leakage and is not, therefore, desirable. The method suggested by Prof. Thompson amounts practically to converting the capacity, S, partly or wholly into insulation conductivity, K, and thus diminishing S/K until it is as small as L/R. The self-induction coils added in this system must not be confounded with the self-induction of the cable L, for they are added as shunts to the cable. The ratio L/R may also be made equal to S/K by adding self-induction coils in series with the cable, thus increasing the value of L ; this is the solution adopted by Dr. Pupin. Here again the ideal solution is only obtained when the self-induction is evenly distributed, but a practical solution can be obtained by placing coils at intervals along the cable.

Dr. Pupin, besides repeating a good deal of Mr. Heaviside's theoretical investigations, worked out the necessary values of the self-induction of the coils and the maximum distance apart at which they can be placed in order to imitate sufficiently well an evenly distributed self-induction. He then proceeded to build some coils and to experiment with them on an artificial cable. The results of some of these experiments are interesting, as they point to the great improvement the addition of the

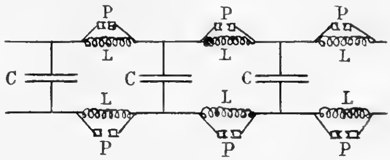

FIG. 8.

inductance produced. An artificial cable was built up with condensers in the usual way in 250 sections, each section representing a mile of cable ; between each section were placed induction coils which could be short-circuited by plugs. A diagram of this cable is given in Fig. 8 ; as before, the capacity is represented as if it consisted of condensers, C,C ; the induction coils are shown at L,L ; these coils are short-circuited by inserting the plugs at the contacts P,P. When all the coils were in circuit telephonic communication could be carried on with perfect ease over the whole length, 250 miles, of the cable ; when, however, the coils were short-circuited conversation was good up to 50 miles only, fair up to 75, impracticable at 100 and impossible beyond 112. It must be remembered in considering these results that the cable was an artificial one and that possibilities of error are consequently great, so that the results must not be transferred with too much confidence to the case of an actual cable.

Apart from this, however, the results are extremely good, and Dr. Pupin is to be congratulated on having obtained experimentally a practically distortionless circuit. It is perfectly true, no doubt, that Mr. Heaviside had obtained the solution already theoretically; but the engineers generally require to have their attention attracted by actual experiment and are not too prone to make changes on a theoretical basis only, however sound. Whether a cable can be commercially constructed on the lines of Dr. Pupin's artificial cable is a question for the practicians ; we have no doubt that, now its advantages have been demonstrated, they will be able to find a way. The enormous advantage of Transatlantic telephony can never

[1] See the *Electrician*, August 1893, p. 439.

for a moment be questioned; it means much more than that we shall be able to telephone to America; it means that we shall be able to telegraph at the speed of the automatic transmitter. The present speed of Transatlantic telegraphy is something like 20 words a minute, and there are 12 duplexed cables having, therefore, a carrying capacity of about 500 words a minute. A single distortionless cable, built on Dr. Pupin's plan and working with an automatic transmitter, would have, therefore, a carrying capacity equal to that of all the existing cables.

INDIGO AND SUGAR.

THE Behar Sugar Commission, which was appointed in October of last year to see whether improvements might not be made in the cultivation and manufacture of cane sugar, has completed its task. The report has been issued with commendable promptitude—scarcely five months having elapsed from the appointment of the Commission to the presentation of its report. The Commission was primarily appointed because of the perilous position of the indigo industry, to see whether it might not be possible to grow the sugar cane and indigo crops in rotation.

The *Times* of April 15 contains an article upon this report. One thing the Commission seems to have made clear is that the methods employed in the sugar industry have been on the same happy-go-lucky slip-shod fashion as those until lately used in the manufacture of natural indigo. The yield of sugar per acre in India averages about one ton, whereas in Barbadoes it is three tons, and four tons are obtained in Java.

The Indian Government, taking alarm at the great increase in the imports of beet sugar and wishing to aid the indigenous planter, imposed countervailing duties in March 1899. The duties have apparently failed in their object, as the imports of beet sugar for 1900 were greater than for 1898. It would appear that very little attempt has been made in India "to treat the soil or plant the canes on scientific principles," and that the methods of refining the sugar are rough, crude and wasteful, so that under such conditions the yield of the finished article is not what it should be, and the quality is poor; Indian sugar is, therefore, unable to compete with sugar refined by modern scientific methods and appliances.

It is further stated that there is an increasing tendency in India to prefer sugar which has been refined to unrefined sugar. The Commission recommend the employment of modern and up-to-date apparatus. We are glad to note that they do not recommend indiscriminate help to the individual planter or refiner, but suggest that such assistance as is desirable should be given in helping systematic experiments at a central station.

Turning now to the indigo industry, which was the primary cause of the appointment of the Commission, we find that the indigo planter, now thoroughly alive to the danger which threatens him, is exerting himself to improve the yield of indigo. In the first place, by the employment of artificial manures, principally superphosphates, an increased plant production of from 50 to 100 per cent. has been obtained. In manufacturing indigo, it will be remembered (NATURE, November 1) that it is usual, when the plant has reached maturity, to cut it near to the ground and to steep the whole plant. After a few months the fresh shoots which have sprung up are again cut, but the yield of indigo from this second crop is inferior to that obtained from the first. It has been suggested, seeing that almost the whole of the colouring matter is contained in the leaves, that the plant should not be cut down, but that the leaves only should be stripped off and steeped. It is calculated that four or five strippings could be obtained during the manufacturing season, and thus a very much larger quantity of indigo would be produced than by the methods at present in vogue.

The old beating process for oxidising the liquors obtained after the plant has been steeped is gradually being replaced by the use of the "blower." In this method air is blown through a number of perforated pipes which are placed at the bottom of the vats, with the result that oxidation is more rapid and complete, and about 25 to 30 per cent. more colouring matter is produced than by the old process. Mr. Rawson, in addressing a meeting of those interested in the indigo industry at Calcutta on February 20, said that the output of indigo in North Behar last year amounted to about 60,000 maunds,[1] and that at least 12,000 maunds more would have been produced had the new "blowing" process been employed.

A manufacturing industry, such as that of indigo, which is to a large extent dependent upon atmospheric conditions, has naturally seen many dark days. But when the supply has been short there has generally been an enhancement in prices. The Commission is of opinion that a rise of price owing to bad seasons or short supplies can no longer be looked for, and say in their report: "It is reasonable to anticipate that the competition of synthetic indigo will prevent any future increase in the price of vegetable indigo, that it will soonest and most injuriously affect the finest and most expensive indigo, which is that of Behar, and cause a further reduction in price, which would hardly clear the planter in a good season, while a bad season would be ruinous to him." They go on to say, "it is obviously expedient that indigo planters should possess in sugar and other products resources which, if they are carefully and intelligently utilised, will enable them to contemplate the future of indigo with equanimity."

In order to aid the Indian indigo industry, the Bengal Government has formally agreed to grant an annual subsidy of 50,000 rupees for three years for further chemical and scientific researches with regard to indigo cultivation.

Indigo planters claim that at present the natural dye can be placed on the market at prices which can undersell the synthetic product. This is good news, but it is difficult to see how it is in the long run to hold its own against the artificial product, which is of uniform quality, requires no grinding, and is unaffected by vicissitudes of weather.

Prof. Armstrong, in a long letter to the *Times*, says that "The truly serious side of the matter, however, is not the prospective loss of the entire indigo industry so much as the fact that an achievement such as that of the Badische Company seems to be past praying for here."

Whether or not the natural indigo industry is to become a thing of the past remains to be seen, but if the replacement of natural indigo by a synthetic article produced in Germany leads British manufacturers to realise more fully the importance of trained scientific assistance, the decline, although in itself a great calamity, might not be entirely without its compensations.

Since writing the above, I have received a copy of an address upon "The Synthesis of Indigo," delivered by Prof. Meldola before the Society of Arts on April 17. In introducing the subject Prof. Meldola says that it is now often considered unpatriotic to "call public attention to any branch of industry in which we are being beaten by foreign competitors." He, however, considers that "The real enemies of British industry are those who, by virtue of their positions as politicians, economists, or as men of science, try to blind the public and to allure the manufacturer and merchant into a fool's paradise of false security."

[1] The Bengal factory maund is 74·66 lbs.

Then follows a very lucid and interesting historical survey of the chemistry of synthetic indigo. Attention is called to the fact that the first patent bears the date of March 19, 1880, and that although we knew that artificial indigo prepared by this, the cinnamic acid synthesis, could not compete with the natural product, yet its appearance caused much consternation among indigo planters. But because the threatened storm did not break, the planters evidently quickly forgot their fright and returned complacently to their old rule-of-thumb methods. Not so the chemists; they steadily and perseveringly plodded on, and in 1882 von Baeyer and Drewson brought out another synthesis, viz. the condensation of acetone and orthonitrobenzaldehyde in presence of caustic alkali. This process, or a modification of it, is employed at the present by the firm of Messrs. Meister, Lucius and Brunning; but as the supply of the raw material—toluene—is limited, Prof. Meldola, speaking as an individual, says: "Were I a planter, I should have no anxiety whatever with respect to a competing product which starts from toluene." Every 1000 gallons of coal tar yields about $6\frac{3}{4}$ gallons of benzene and $3\frac{1}{4}$ gallons of toluene, therefore any process which started with benzene as the out-going product should be better able to compete than one in which toluene is the starting material. However, although there are several syntheses which start from aniline (produced from benzene), the methods employed are so costly that at present the planter has very little to fear in this direction.

Naturally the chief portion of the paper is devoted to Heumann's synthesis, as at present worked by the Badische Company. This process, which starts from naphthalene, the supplies of which are practically unlimited, was described in NATURE, November 29.

In his references to the Badische Company Prof. Meldola quoted the following facts from the official report prepared for the Paris Exhibition:—

"The factory at Ludwigshafen employs 148 *scientific* chemists, 75 engineers and technical experts, and 305 members of the mercantile staff. In 1865 they commenced with 30 workmen, and they now employ over 6000. The consumption of coal is about 243,000 tons per annum; water is supplied to the factory to the extent of some 20,000,000 cubic metres annually; they make 12,000,000 kilogrammes of ice, and over 12,000,000 cubic metres of coal gas in the course of the year. The electric installation consists of eight dynamos, the currents from which serve for illumination, motive power and electrolytic processes. Steam is supplied from 102 boilers, which serves for heating purposes and for driving 253 steam engines."

Let the British manufacturer and the Indian indigo planter try to digest these hard facts and figures. I wonder whether there are 148 *scientific* chemists employed by manufacturers in the whole of the United Kingdom. Let them also remember that these figures only refer to *one* firm.

Finally, Prof. Meldola refers to the natural product *versus* synthetical indigo. He is unable to hold out the hope that the natural article will in the long run be able to compete with the product of the German factory. "The planters have allowed twenty years of activity on the part of the chemists to pass by with apathy and indifference, and at the last moment only have they called in expert assistance."

It is truly marvellous that only the British planter should have been so lethargic. In Java the Dutch planters "have had the wisdom to avail themselves of the resources of the botanical gardens for experimental purposes, and their chemists and bacteriologists working in Holland in co-operation with the planters have, as is well known, for many years past been contributing to chemical literature the results of their investigations."

Reference is made to the contradictory opinions as to what goes on in the steeping vats, as to whether the resolution of the glucoside indican into indigotin is due to bacterial fermentation, or whether it is one of ordinary zymolysis. Attention is also directed to the drying process, which often extends over several weeks, and during which time it is stated that a fungus grows on the cakes and ammonia is evolved. Prof. Meldola asks whether this may not be due to the destruction of indigo by a micro-organism. I have myself often wondered that in all the suggestions for improving the yield and quality of indigo no one appears to have drawn attention to this apparent decomposition. It seems possible that more thorough washing and rapid drying in a current of hot air would perhaps prevent this. In his closing remarks Prof. Meldola refers to the antiquity of the industry, and questions whether the methods at present employed in India are very different to those used in the time of the Pharaohs.

F. MOLLWO PERKIN.

THE OLDER CIVILISATION OF GREECE.[1]

THE sixth volume of the *Annual of the British School at Athens* contains matter of extraordinary interest to students of the history, not only of Greece, of Egypt and Western Asia, but also of mankind in general. The culture which now dominates the world is the child of the civilisation of Ancient Greece, and any archæological discovery which tends to increase our knowledge of the beginnings of Greek civilisation possesses an importance and an interest far greater than that of any other possible discovery whatever in the archæological field.

For the last twenty years, since Schliemann first unveiled the treasures of the citadel of Mycenæ, it has been recognised that the culture of classical Greece as we know it is but the second epoch of Greek civilisation. Classical Greece had a past the true history of which had been half forgotten, had been preserved in confused and contradictory legends. The culture of the past had bloomed from end to end of the Greek world, in cities, some like Athens or Knôssos, of renown in classical as well as præ-classical days, others like Mycenæ and Tiryns, cities whose fame ceased to be when the Dorians entered Greece. This culture was bronze-using, and was, in fact, the Greek phase of the European culture of the Bronze Age, a phase earlier in date than the phases of Central and Northern Europe, and in all probability not only their forerunner, but to a great extent their forbear. This culture itself developed out of a stage of transition from Neolithic barbarism, which we call "præ-Mycenæan," during which stone, copper, and occasionally bronze, were used side by side, pottery was rude and unpainted, and the dead were buried in *cist-graves*. This stage shades off on the one side (as in the first city of Troy) into the Neolithic culture, on the other (as in Cyprus) into Mycenæan civilisation, which marks the first stage of real "civilisation," properly so-called, in Europe. The earliest stages of the Mycenæan culture are known to us from discoveries of settlements with pottery, &c., in Thêra, at Phylákopê in Melos, at Kamárais in Crete, and other isolated spots, chiefly in the Southern Ægean islands. The civilisation which we find at Mycenæ, at Vaphio, at Ialysos and elsewhere, is the same as that of Phylákopê and Kamárais, but is more highly developed in many ways. This can only be the culture of the heroic Achaians, which was overthrown by the Dorians; its date must, then, be placed certainly before 900 B.C., even if, as is very possible, it continued to exist in Western Asia Minor and Cyprus till the eighth century. We can be more certain about its date than this; Mycenæan culture was by no means confined to

[1] *The Annual of the British School at Athens*; No. VI. Session 1899–1900. Pp. viii + 156. With illustrations and two maps. Printed for the subscribers and sold on their behalf by Macmillan and Co., Ltd. Price 10*s*. 6*d*.

Greece, and there were ships and sailors in those days as bold and venturesome as any of the time of Elizabeth. We know from the Egyptian State archives of the reign of King Akhunâten (B.C. 1430; date determined by synchronism with Burraburiyash of Babylonia, B.C. 1430) that in the XVth century B.C. the Phœnician cities already traded with many lands across the seas, with Egyptian Thebes, with Alashiya or Cyprus (?), and with *Keftiu*. The people of *Keftiu* came to the court of King Thothmes III. of Egypt (B.C. 1550) with gifts.

Where was *Keftiu*? Mr. A. J. Evans tells us this in this sixth volume of the *Annual of the British School at Athens*.

Mr. Evans's excavations at Kephala, the site of Knôssos, in Crete, are the culmination of many attempts, pursued during several years past under difficulties of all kinds, to elucidate the early history of Greek civilisation in Crete. The traditions of the island point to its having occupied a position of especial prominence in the Mycenæan world, and Mr. Evans's hopes of great results from Cretan exploration have not been disappointed. He has not only discovered at Knôssos a Mycenæan palace of the first rank, which is very probably identical with the legendary "Labyrinth" of Minôs, but has also discovered that the Mycenæans of Crete were in all probability the same people as the "Men of *Keftiu* and of the Isles in the midst of the Very Green" (*i.e.* the Mediterranean), who make their appearance in Egyptian history *c.* 1550 B.C., thus giving the earliest trustworthy date for the Mycenæan civilisation.

Not only the palace, but also the Mycenæan town of Knôssos was discovered in the course of these excavations. The exploration of the town ruins was carried on by Mr. D. G. Hogarth, late Director of the British School at Athens, Mr. Evans busying himself more especially with the exploration of the palace. It is noteworthy that vases and fragments of vases found in the town ruins were of the early Mycenæan or "Kamárais" type, while those found in the palace mostly belonged to the fully-developed Mycenæan types so well known to students of early Greek art from the great work of Messrs. Furtwängler and Löschcke. This does not necessarily mean that the town-ruins are all older than the palace; all that is implied is that the palace, which from various indications was evidently already in existence in the "Kamárais-period," continued to be occupied down to the period of its sudden sack and destruction by fire towards the end of the Mycenæan age, at which time only vessels of the later type were in use, while in the town we have two strata of settlement, the one containing the vases of the earlier period, the other those of the later generations of inhabitants. There need be no question of a change of race here, though Mr. Hogarth seems to suggest it. Alteration of style in art is no proof of racial change. Such changes are simply due to an alteration of fashion, suddenly started by some artist. We have an example of a sudden alteration of the kind in Egypt in the early years of the XVIIIth Dynasty. But we do not therefore in this case assume the violent substitution of one race of inhabitants by another. Even alteration of burial customs is no clear proof of change of race.

Important as the relics of the "Kamárais-period" from the Knôssian town are, however, they pale before the importance of the discoveries made in the palace itself. The excavation of this, probably the most important Mycenæan building yet discovered, is only begun, and we know not how Mr. Evans may increase our knowledge of the older civilisation of Greece in the course of his diggings this year. What he found last year, however, gives us material enough to think about! The plan of the palace shows a vast labyrinth of chambers, halls, corridors and passages; a true labyrinth indeed, for it is the only genuine and original Labyrinth itself, as the constantly-recurring symbol of the double-axe, the emblem of the later Zeus of Λαβραυ-νδα, which is etymologically the same word as Λαβύρι-νθος, "The Place of the Λάβρυς or Double-Axe" (for the earliest Mycenæans of Knôssos and elsewhere were not Aryan Hellenes, but "Pelasgians" allied to the non-Aryan peoples of Asia Minor), the emblem of the Knôssian Zeus, Ζεὺς ἄναξ, Πελασγικὸς, shows. This is the labyrinth of Minôs: is the bull-headed Minotaur, child of Zeus, of whom legends passed to the succeeding Hellenic inhabitants of the land, the recollection of some Mycenæan deity to whom human sacrifice was offered at Knôssos? We know the love of the Mycenæans for bulls, we see the *protomae* of bulls at Mycenæ and among the gifts of the *Keftiu*, we find pictures of ταυροκαθάψια, bull-catching, at Tiryns and elsewhere, we have the splendid life-sized relief of a bull's head in painted *gesso duro* from Knôssos itself (Fig. 10

Fig. 1.—Protomycenæan Vases from Knôssos: probable date before 1600 B.C.

of the work under review); there are hundreds of other instances. The bull was the beast of Zeus: the idea of a Phœnician origin of the Minotaur is just so much rubbish; he is a purely Mycenæan conception. And his master, Minôs? What would Mr. Grote have said had he been told that in 1901 the name of Minôs would pass

FIG. 2.—The Fifth Magazine, showing Great *Pithoi* and Receptacles in the Floor.

from the realms of pure myth into those of historical probability? Yet we have what look very much like the remains of a great Cretan power dating long before the Return of the Herakleids, in fact the power and kingdom of Minôs. The evidence of Greek legend can no longer be scoffed at, and the tradition of the Minoan thalassocracy may yet be shown to contain a substratum of historical fact. Those *Keftiu* went far afield: they reached Egypt. Sicily and Kamikos are no farther.

The records of Knôssos have much to tell us, but as yet they are dumb. There they lie before us, those queer characters incised on tablets of sun-baked clay, but we cannot read them yet. How long we shall continue in this state of tantalising ignorance it is impossible to tell. The lamentable failure to read the so-called "Hittite" script of Eastern Asia Minor is no good augury. This discovery of inscribed tablets is the most important in the field of early Greek antiquities since the excavation of the graves at Mycenæ. The tablets, good illustrations of which are given by Mr. Evans, were found in a number of deposits or "hoards" in the palace, mostly packed away in sealed boxes placed in large πίθοι or handleless vases (a specimen of the kind, brought from Rhodes, is in the First Vase Room of the British Museum), which were stored in special chambers. The writing is of two kinds, hieroglyphic ("pictographic") and linear: in both remarkable resemblances to Egyptian characters are noticeable, and give further proof of the idea, now fast gaining ground, that Egypt exercised no little influence upon the development of Mycenæan culture. On the other hand, the use of clay for the tablets is a sure sign of the influence of the rival civilisation of Babylonia. Many of the tablets evidently contain simply lists of ships, chariots, horses, swine, &c.; so much we can guess from the pictures. The numerical system is evident; further than this we cannot go. It had long seemed curious that the highly-developed civilisation of Mycenæan days should have been ignorant of the art of writing; but we had no conclusive proof of Mycenæan writing before Mr. Evans's epoch-making discovery. Now here are the records of the Mycenæans before our eyes; σήματα λυγρά, indeed! They will not want for energetic "Bearbeitung," and the Clarendon Press is already preparing a fount of Mycenæan type! But the omens are bad.

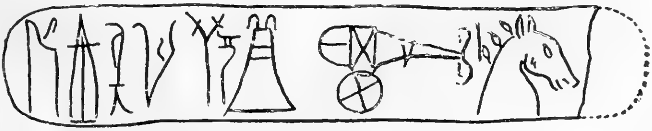

FIG. 3.—Linear Tablet referring to Chariot and Horses and, perhaps, Cuirass. (Size of original.)

We have remarked that Mr. Evans has shown that the *Keftiu* who brought gifts to the court of Thothmes III. of Egypt, *c.* 1550 B.C., were Mycenæan Cretans. This conclusion is a legitimate one. Some of the finest known examples of Mycenæan fresco-painting have been found in the Knôssian palace, and among them are representations of processions of men bearing vases, &c., who in dress are absolutely identical, on the one hand, with the bull-catchers of the Vaphio cups, on the other with the *Keftiu* who are depicted on the walls of Rekhmarā's tomb at Thebes, in Egypt. No doubt of the identity is possible; the further presumption that the pictures of Rekhmarā's tomb are roughly contemporaneous with the frescoes of Knôssos is backed up by the cumulative force of all the rest of the chronological evidence, besides being inherently probable from the almost exact similarity of costume, &c. The date of *c.* 1550 B.C. for the *later* portions of the Mycenæan palace at Knôssos is thus clearly indicated.

These frescoes give us an inkling of the racial type of the Mycenæans. They are not fair-haired Aryans at all. They are brunett, black-haired, un-Aryan people like the modern Italians, Greeks and Anatolians; they belong, in effect, to the "Stirpe Mediterranea" of Sergi, the race which we may, if we like, call Pelasgian, which preceded the Aryans in Greece as well as in Asia Minor, and of whose peculiar language-type Karian and Lycian give us a good idea. The Aryan conquerors gave Aryan languages to Italy, Greece and Phrygia, but the modern speakers of Italian, of Greek, and of Armenian much more closely resemble their non-Aryan ancestors than their Aryan conquerors.

The palace of Knôssos was built of great gypsum and limestone blocks, and when complete must have been a most imposing building. One of the most curious facts with regard to it is that it is really built round a small open space, which Mr. Evans speaks of as "The Central Clay Area." "This enclosure," says Mr. Evans (p. 17) "turned out to be entirely devoid of foundations, and its floor was composed of the pale clay already noticed as being of artificial accumulation and as probably due to the disintegration of the clay platforms and wattle-and-daub huts of a very primitive settlement. It was found to be full of Neolithic relics, and a shaft sunk near the N.W. corner showed that the deposit was at this point 7·50 m. in thickness. On the south side this clay deposit merges in a darker soil full of wood-ashes and bones, possibly of a sacrificial nature. The existence of this early site, untouched in the middle of the later palace, suggests curious speculations. We have here, perhaps, the interior of a *temenos* preserved for religious reasons, and the square base of an altar, already noticed, in the eastern bay of the enclosure, confirms the idea of consecration. It may be that the 'Palatine' of Mycenæan Knôssos also had its 'Casa Romuli'—a sacral survival of a prehistoric dwelling."

A chamber of great importance in the palace was the Throne-room, of which Mr. Evans gives a description (p. 35 ff.): "The chamber . . . was in many ways as perfect as the room of a Pompeian house, though some fourteen centuries earlier in date. On the south side opened an impluvium and steps leading down to a fine stone tank. . . . . Breasting this, and along two other sides of the room, ran gypsum benches with pilasters. . . . At the middle of the north wall was an interval between two of these stone benches, the central post of which was occupied by a gypsum throne. The throne rested on a square base and displayed a high back of undulating leaf-shaped outline. . . . Its total height is 1·06 m., and the level of the seat 0·56, or 21 cm. above that of the stone benches. . . . The lower face of the throne presented a curious architectural relief, consisting of a double moulded arch springing from flat, fluted pilasters, expanding upwards in the Mycenæan fashion. The upper part of this arch was traversed by a moulded band forming a counter-curve. But the most interesting feature remains to be described. The lower part of the mouldings of the arch on either side were, by a strange anticipation of later Gothic, adorned with bud-like crockets. The architectural features, indeed, revealed by these reliefs are in almost every respect unique in ancient art."

FIG. 4.—Throne-Room as seen from Antechamber.

A splendid idea of this room and of the now famous "Throne of Minôs," can be obtained from the photographs published in the *Annual*, one of which is shown in Fig. 4. In general it may be said that the illustrations are extremely good—the plans also. But for finality in these latter we must wait till Messrs. Evans and Hogarth have brought their excavations to an end. Enough has now been said to give the reader an idea of the immense importance of the discoveries at Knôssos, and it is a matter of congratulation that their discovery has fallen to the lot of an Englishman. Our knowledge of early Greek civilisation in Crete now rests on a much surer foundation than it did when Mr. Evans strove to draw a connected story from the evidence of the "Seal-stones" alone.

To one small point only in Mr. Evans's discussion of his discoveries must we take exception. When speaking of the inscribed tablets he says (p. 57): "Some distant analogy may be recognised with the tablets of Babylonia, but the letters here are of free upright 'European' aspect, far more advanced in type than the cuneiform characters. They are equally ahead of Egyptian hieroglyphs, though here and there the pictorial original of some of these linear forms can still be detected." This passage is very incomprehensible. In the first place the whole idea of the Knôssian tablets is obviously of Babylonian origin: they are not merely "distantly analogous" with the tablets of Babylonia. In the second place, what does Mr. Evans mean by the Mycenæan letters being "of free upright 'European' aspect"? What characters can be called free or unfree? Why is the erect position specially "free" or "European"? The Egyptian hieroglyphs and their hieratic developments stood bolt upright unless a crocodile or a snake were pictured; cuneiform was upright and spiky enough, in all conscience. They are not European. With what European script is he comparing the Mycenæan writing? Surely not with the Greek alphabet, which was of Phœnician, and ultimately of Egyptian, origin. And how are the Knôssian characters more advanced in type than the cuneiform characters? Obviously they are nothing of the kind; they are in the same stage of development as the Egyptian hieratic writing, to which they bear a strong resemblance; so far, then, it may be said that they are "ahead" of the Egyptian hieroglyphs; but cuneiform was far more conventionalised, far "ahead" of either Egyptian hieroglyphic and hieratic or Mycenæan linear. The people who used the Knôssian script may turn out to have had not one drop of Aryan "European" blood in them, and European-Greek culture may be as thoroughly of non-Aryan (and equally non-Semitic) origin as Semitic culture was in its origin absolutely non-Semitic.

The work of Messrs. Evans and Hogarth at Knôssos has been supplemented by the latter with the very interesting results of his excavation of the famous cave of Zeus on Mount Diktê, an account of which appears on p. 94, ff. Mr. Hogarth's story of his operations, of the blasting of the rocks, the unveiling of the most ancient sanctuary of Zeus, the recovery of small bronze double-axes and other votive objects, belonging to the same period as the Knôssian palace, from the crevices of the stalagmitic deposit in which they had remained undisturbed for nearly four thousand years, the finding of a little Egyptian bronze statuette of Amen-Rā, which shows that somewhere about 1000 B.C. King Zeus was already identified with Amonrasuntiru, Amen-Rā, king of the gods—all this is of the highest archæological interest, and may be recommended to the notice of students of Greek religion.

It remains to speak of the articles of less importance which also find a place in this number of the *Annual*. That by Mr. F. B. Welch on "The Influence of the Ægean Civilisation on South Palestine" is important as chronicling the occurrence of Mycenæan pottery at a Palestinian site, Tell es-Safi. "This," says Mr. Welch, "was certainly a Philistine stronghold, a fact which is suggestive in view of the probable north-western origin of the Philistines" (p. 119). This is quite true, and it may be remarked that the old tradition of the Cretan origin of the Philistines has lately, in view of the Egyptian records of attacks by the Peoples of the Sea, among whom figure the *Pulesatha* or Philistines, and a great deal of other evidence, both archæological and legendary, come once more to the front, and probably represents a historical fact. But Mr. Welch should note that Semitic authorities such as Delitzsch, Jensen, Mayer and Tiele uncompromisingly claim the Philistines as Semites, and specifically Aramæans. The Egyptian evidence, however, as Mr. Welch rightly implies, goes absolutely against the Semitic claim, which will probably have to be given up. Still, the Greek archæologists have no right to ignore the opinion of the Semitists on such a question as this. Mr. Welch seems, by the way, to attach rather too much importance to purely "typological" arguments derived solely from the study of pottery, which can never be an absolutely infallible guide.

Mr. J. C. Lawson's note on "A Beast-Dance in Scyros" (p. 125) will be of great interest to anthropologists. In carnival time the young men of Scyros array themselves in goat-skin capes—"each does his best according to his lights and his means to look like a goat"—hang goat-bells round their persons and solemnly dance through the town, often stopping "at some friendly door to imbibe spirituous encouragement to further efforts." This is undoubtedly a very ancient survival, and possibly goes back to Mycenæan times, a surmise with which anybody who knows what a great part goat-headed and other theriomorphic figures play in Mycenæan art will probably agree. But alas, "thanks to the steadily increasing influx of Western culture during the last few years," the goat-mask is often replaced nowadays by "an Ally Sloper mask"! The modern Japanese wears a billycock or a deerstalker on the top of his national historical costume. So the free and upright civilisation of modern Europe dominates the world!

It may be finally noted that the knowledge which the contributors to this number of the *Annual* possess of the German language appears to be defective. If German terms are used at all, their proper plural forms should be given to them. "Bügelkannes" may be Dutch, but is neither German nor English; Mr. Welch gets over the difficulty, which might have been solved by reference to a German grammar, by giving his German words no plural form at all. He speaks of "Bügelkanne" and "Schnabelkanne" when he means *Bügelkannen* and *Schnabelkannen*.

Despite these little imperfections, the sixth number of the *Annual of the British School at Athens* is undoubtedly the most important contribution to our knowledge of the early history of mankind that has appeared for many years.

MAGNETIC OBSERVATIONS DURING TOTAL SOLAR ECLIPSE.

THE effect produced by a solar eclipse on the meteorological conditions of the atmosphere has on many occasions in the past been the subject of observation, but in the number of *Terrestrial Magnetism* just received we find an account[1] of a systematic examination of the influence of such an eclipse on magnetic conditions also. It had appeared to Dr. Bauer, chief of the U.S. Magnetic Survey, that magnetic observations might on such an occasion be usefully undertaken; and the occurrence of the solar eclipse of May 28 of last year, the total phase of which was visible in the United States, afforded an excellent opportunity of carrying such design into execution. For the needs of the magnetic survey simultaneous magnetic observations are made on certain days throughout the year at the different magnetic stations, and it was arranged that such observations should be made, on the day of eclipse, at stations as near as possible to the path of totality. Six stations were selected; three of them—Union Springs, Rocky Mount and Cape Charles—were situated within the path of totality, the remaining three—Salem, Bayard and Gaithersburg—being outside. The observers received instructions to occupy such stations as their special work permitted for the due accomplishment of the object in view, accompanied by a detailed scheme of the observations to be made. The prescribed course was carried out by all the observers excepting the one at Gaithersburg, who for some reason failed to receive his instructions in time; but he made observations according to directions sent him previously, relating to other work. The detailed scheme of observations is given with the view of aiding observers making preparations for similar work on future occasions. The observations made are discussed at considerable length, being accompanied by numerous graphical illustrations, and it is stated that there can be no question that some kind of magnetic disturbance made itself felt on May 28 at every one of the stations.

Finally, the conclusions arrived at are given under eleven separate heads, the principal points of which are contained in the following summary:—A small magnetic oscillation made itself felt at various stations situated in the eastern part of the United States during the time of the eclipse. It was detected by various persons, at various stations, with different instruments, under different conditions, and was also automatically recorded.

[1] *Résumé* of magnetic observations made chiefly by the United States Coast and Geodetic Survey on the day of the total solar eclipse May 28, 1900.

The various phases of the oscillation did not take place at the different stations at the same absolute time, or local time, but in every instance were associated with the time of maximum obscuration of the sun. The duration of the oscillation was apparently about the same as that of the eclipse, about two and a half hours. The range of the oscillation was about one minute in arc for declination, and about eight units in the fifth decimal C.G.S. for horizontal intensity, that is, to about 1/2800th part of the absolute horizontal intensity. The general effect was to deflect the declination needle to the west, and decrease the horizontal intensity, before the time of maximum obscuration, the movement afterwards being in both cases in the opposite direction. The analysis indicates that the cause producing the magnetic oscillation was situated outside of the earth's crust, the presumption being very strong that the oscillation is to be referred to some change produced in the upper atmospheric regions by the abstraction of the sun's rays, due to interposition of the moon.

Dr. Bauer expresses himself as having been in doubt before making the observations as to whether any magnetic effect referable to the eclipse would reveal itself, and adds that he was afterwards slow to conclude that the magnetic oscillation observed was not accidentally connected with the eclipse, until he had made such exhaustive examination of every point involved as justified him in formulating a definite conclusion. The result is interesting, and makes it desirable, as he says, that every opportunity should in future be taken to obtain, during eclipses, simultaneous magnetic, atmospheric-electric and meteorological observations at as many stations as possible.

It is to be remarked that, although Dr. Bauer eventually speaks with some confidence as to the magnetic movement observed having relation with the eclipse, the movement in question was small, and, abstractedly speaking, much too small on which to found any certain conclusion, considering the abundance of magnetic movements of similar and even greater magnitude. The circumstance that seems really to give weight to the conclusion drawn is the statement that the various phases of the magnetic oscillation were associated with the time of maximum obscuration of the sun. Confirmation of this circumstance is therefore what is now to be desired.

Following the paper there is printed an appeal for international co-operation in magnetic and allied observations during the total solar eclipse of May 17 next.

WILLIAM ELLIS.

PROF. H. A. ROWLAND.

HENRY AUGUSTUS ROWLAND was born in 1848. He was educated as an engineer, and graduated at the Rensselaer Polytechnic at Troy, New York, in 1870. After one year's experience as a railway engineer on the Western New York line, and a second spent as instructor in natural science at Wooster, Ohio, he returned to his college to share in its teaching, becoming an assistant professor in 1874. Two years later, in 1876, after spending a year under Helmholtz in Berlin he took office as the first professor of physics at the newly founded Johns Hopkins University. Baltimore remained his home until his death, on April 16, at the early age of fifty-three years.

His work at Berlin on the magnetic efforts due to a moving body when carrying an electric charge brought him at once into fame. The result was published by von Helmholtz in 1876, and is thus described by Maxwell in a metrical letter to Tait, written in June, 1877. Tait had inquired, also in verse, as to the electric effects to be expected if a disc of ebonite carrying a charge were made to rotate in its own plane, and Maxwell writes :

> The mounted disk of ebonite
> Has whirled before nor whirled in vain,
> Rowland of Troy, that doughty knight,
> Convection currents did obtain,
> In such a disk, of power to wheedle
> From its loved north the subtle needle.

Rowland showed by the direct effects produced on a magnetic needle that a charged body in motion gave rise to a magnetic field just as though it were a current whose strength depended on the product of the charge and the velocity.

This result is of fundamental importance to electrical theory ; it was confirmed by Rowland and Hutchinson in 1889, and has been generally accepted as an established fact. Within the last few months, however, Cremieu has published an account of a repetition of Rowland's experiments which has led him to a negative result ; the question just at the present moment appears to need further investigation.

Rowland's appointment at Baltimore was rapidly followed by a series of brilliant researches, each of the first importance. His determination of the unit of resistance came first. This was published in 1878. The original B.A. units were constructed by the Electrical Standards Committee in 1863-4 to represent 10^9 C.G.S. units of resistance ; according to Kohlrausch's results in 1870 they were 2 per cent. too high, while according to Lorenz (1873) they were 2 per cent. too low. Rowland's paper contains an able criticism of the old experiments and a detailed account of his own which led him to the number $\cdot 9912 \times 10^9$ C.G.S. units as the value of the B.A. units. Further experiments in 1887 reduced this to $\cdot 9864 \times 10^9$. The value now generally accepted is $\cdot 98653 \times 10^9$. Rowland himself employed a modification of Kirchhoff's original method, in which the induction current in a secondary circuit produced by reversing a measured primary current in a neighbouring circuit is observed.

In 1879 Rowland presented to the American Academy of Arts and Sciences his paper on the mechanical equivalent of heat, with subsidiary experiments on the variation of the mercurial from the air thermometer, and on the variation of the specific heat of water. To attempt to give any account of the contents of this classic work would occupy too much space. To appreciate its value and to realise the skill and the ingenuity of its author it must be studied itself. More is known now about exact thermometry and the precautions necessary in using a mercury thermometer, and so it has come about that some corrections are necessary in Rowland's work, specially in that part of it which deals with the relation between the scales of the mercury and the air thermometer. These corrections were made at the Johns Hopkins University by Messrs. Day and Wardner and Mallory ; but this fact detracts nothing from the importance of his investigation, and among the many determinations of the value of Joule's equivalent, Rowland's will always remain in the first rank.

Passing over, for the present, much work of great value, among which we may note his investigations into the magnetic permeability of various substances, published in the *Philosophical Magazine* for 1873 and 1874, and his theory of Hall's effect, we come next to the year 1882, when Rowland gave to the Physical Society of London an account of his concave grating. This is published in the *Philosophical Magazine* for September, 1883.

The results of this discovery are well known. A new weapon was placed in the hands of spectroscopists ; it became possible to photograph spectra directly without the use of prisms or lenses, and with a greatly increased dispersion and resolving power ; the beautiful maps issued at a later date by Rowland himself, and by Higgs of Liverpool, are striking evidences of the value of the grating ; the additions to our knowledge arising from this one discovery are already enormous ; much has been achieved which, without it, would have been impossible.

Rowland's own researches with his grating are summed up in his map of the solar spectrum and his table of the wave-lengths of the elements, published in 1893 (*Phil. Mag.*, July, 1893, reprinted from *Astronomy- and Astro-Physics.*)

Of late years he gave much time and attention to a system of multiple telegraphy; this was shown working at the Paris Exhibition last year.

Enough has been written, perhaps, to indicate the debt physical science owes to Rowland; it is said he never received any regular instruction in physics; he was an engineer, and to this, in great measure, his success is due. The accuracy of his work on the ohm depends on the care he took to construct his induction coils so that their dimensions could be accurately measured; he dealt with the determination of the mechanical equivalent as an engineering problem; he employed a large mass of water and used steam power to rotate his paddle at a speed sufficient to make the resulting rise in temperature one that could be measured with accuracy.

The theory of the concave grating was his, but its success was due to the fact that Rowland had made an almost perfect screw; the method he employed in this in given in his article, "Screw," in the "Encyclopædia Britannica."

He lived for his work, but in his earlier days he was passionately fond of riding. Some years after the publication of the paper on the mechanical equivalent he was awarded a prize for it by one of the Italian Academies; about the same time he won a steeple chase, riding his own horse; he hardly knew which event gave him the greater pleasure. Another time, passing through England on his way home from the Continent, he had three days to spare. One of these was passed at Cambridge discussing electrical measurements, the other two were spent in a hurried visit to Exmoor to get a run with the staghounds. Twenty years ago he was a frequent visitor to England, and attended several of the meetings of the British Association; recently his visits were much less frequent. His friends here were aware that he was not well; some few weeks ago it was known that he had had a serious illness, but the news then was that he was better and on the road to recovery; however, an operation proved necessary, and he never recovered from its effects.

Thus within the last few months physical science is the poorer by the deaths of two of the most brilliant of the followers of Maxwell—Fitzgerald and Rowland; two who were foremost among those who have given to the theory of Faraday and Maxwell the right to claim the position of the theory of the electro-magnetic field.

R. T. G.

PROF. FRANÇOIS MARIE RAOULT.

FRANÇOIS RAOULT, professor of chemistry at Grenoble, died there on April 1 after a short illness. In him France has lost one of her most distinguished men of science, whose discoveries have supplied material for theoretical considerations which, within the past fifteen years, have had a most profound influence on chemistry and physics.

Raoult was born on May 10, 1830, at Fournes (Nord). His father, an officer in the local customs' service of Villers Cotterêts (Aisne), sent the boy to school at Laon, with the intention of his afterwards entering Government service. But Raoult's tastes lay in a different direction; and with the full consent of his father he finished his school career at Paris, and entered the scholastic profession. He began his teaching career at the age of 23 in the Lycée at Reims, and was shortly afterwards transferred to the Collège of Saint Dié; while there he graduated as B. ès Lettres, and B. ès Sciences, passed his "Licencié" examination, and was appointed "Agrégé" of special secondary instruction. On presenting a thesis on "The Electromotive Forces of Voltaic Cells" he gained the title of "Docteur ès Sciences Physiques," and four years later, in 1870, he obtained the chair of chemistry at Grenoble, where he passed the rest of his life in constant labour in teaching and research during a period of 31 years. In 1889 he was elected "doyen," or dean of the faculty, and was re-elected to this important office four times. He occupied himself largely during the last dozen years in the reorganisation of the Faculty of Science, leading to the creation of a local university at Grenoble in 1896.

The author of this notice was once informed by Raoult that he independently discovered Faraday's and Ohm's laws; he had begun to experiment on the passage of electricity through solutions before he had acquired any real knowledge of what had already been achieved. On mentioning the fact to his scientific friends at Paris he learned, to his great disappointment, that his discoveries had been anticipated; but he took comfort in the thought that if he were able to make such discoveries, of which the importance is universally recognised, he must also be able to advance science in other directions. His first scientific work, published as his thesis for the doctorate, has already been mentioned; it was published in 1863, and until 1870 he devoted himself to a study of the chemical effects of the electric current, trying to distinguish between the heat evolved by chemical reactions and that due to the electric current in the voltaic cell. From 1870 to 1886 his attention was given to subjects of a more purely chemical nature, such as the extent of inversion of cane sugar under the influence of solar radiation; the absorption of ammonia by saline solutions; the presence of copper and zinc in the animal organism; the carbonates of calcium, strontium and barium; and the influence of carbonic anhydride on respiration. His work on the absorption of ammonia led him to consider the freezing-points of the saline solutions of that gas (1878); and from that date onwards he busied himself with the freezing- and boiling-points of solutions in water and in other solvents of salts and organic compounds, publishing his results in no less than 57 memoirs in various scientific journals. His last publication, "La cryoscopie," was published in the present year (*Collection Scientia*, Carré et Naud).

Most of Raoult's apparatus was constructed with his own hands; he was rather given to accurate experimentation than to the evolution of theories. The vast mass of evidence which he accumulated relative to the lowering of the freezing-points and of the vapour-pressures of solvents by the presence of dissolved substances made it possible for van 't Hoff to draw the important deductions relative to the connection of these phenomena with osmotic pressure and with the ionic theory of Arrhenius, which will ever shed lustre on his name. And to the practical chemist Raoult's work furnished a means of determining the molecular weights of non-volatile substances—methods familiar to every student of chemistry.

His labours met with ample, though tardy, recognition. In 1889 he was awarded the *Prix Lecaze*, of 10,000 francs; and in the same year he was made *correspondant de l'Institut de France*. In 1895 he received the biennial prize of the Institute; in 1892 he was the Davy medallist of the Royal Society, and in 1898 he was elected a Foreign Fellow of the Chemical Society of London. He was chosen *Chevalier de la Legion d'Honneur* in 1890, raised to *Officier* in 1895, and last year obtained the much-coveted title of *Commandeur*. He was a member of many foreign academies and scientific societies.

Though modest and retiring, Raoult's devotion to his work, dignity of character and sweetness of temper gained him many friends. He was not an ambitious man, but was content to work on, happy if his discoveries contributed to the advancement of science. It is to the labours of such men that the progress of the world, both scientific and industrial, is due; for the methods which he introduced have led, not merely to a knowledge of the structure of many compounds which would otherwise have remained unknown, but have also had a profound influence on chemical theory, and have led to many discoveries of the utmost practical utility. He lived a happy and contented life, and even in his death his desire was satisfied; for in his discourse at the grave of his predecessor in the office of dean of the Faculty of Science at Grenoble, Lory, he gave utterance to the words:—"Puisque la mort est inévitable, ne vaut il pas mieux tomber ainsi tout entier, que de sentir la diminution lente et progressive de ses forces et de son intelligence?" Raoult died, after a few days' illness, without pain.

W. R.

DR. A. HIRSCH.

INFORMATION has reached us from the president of the Council of State for the Republic and Canton of Neuchâtel of the death, at Neuchâtel on April 18, of Dr. Adolph Hirsch, aged 71, the director of the observatory at Neuchâtel since its foundation in 1859. Dr. Hirsch was also secretary to the International Committee of Weights and Measures, established at Paris under the Metric Convention of 1875.

Dr. Hirsch contributed largely to our knowledge astronomy and meteorology, his earlier papers on the former subject having appeared in Berlin and Vienna, and his later papers, particularly with reference to the establishment and position of the new observatory in the Neuchâtel *Bulletin*. ("Établissement de l'Observatoire à Neuchâtel," *Bul.* v. 1859–1861; "Recherchés sur des Pendules Astronomiques," *Bul.* v. 1859–1861; "Découverte de deux nouvelles petites planètes," *Bul.* v. 1859–1861; "Rélation des phénomènes météorologique avec la marche des instruments magnétiques," *Bul.* vi.; "Influence des taches du Soleil sur la temperature de la Terre," 1877; Sur le passage de Venus," 1883, etc.). In more recent years Dr. Hirsch has been closely identified with the introduction of the metric system of weights and measures as an international system. He was a member of the original Commission International du Metre of 1872, of which the present eminent director of the Imperial Observatory, Dr. W. Foerster, and Dr. Von Lang, of the University of Vienna, were also members. On the establishment of the new International Committee of Weights and Measures in 1875, Dr. Hirsch became its secretary, a position which he filled until his death. A master in metrological science and a prince of secretaries, his loss will be deeply deplored by all whose opportunity it was to seek his valuable advice and to be guided by his profound experience.

NOTES.

THE gentlemen's soiree of the Royal Society will be held next Wednesday, May 8. The ladies' conversazione will not be held this year, in consequence of the death of Queen Victoria.

THE position of affairs at Coopers Hill College is most unsatisfactory. We understand that the Members of Parliament who are interested in the higher education of the country had obtained permission to move the adjournment of the House in order to discuss the latest report on the management of this institution laid before Parliament by Lord George Hamilton, but that some M.P., presumably at the instigation of the India Office, which shuns inquiry, has "blocked" this permission. This proceeding, which, unfortunately, the rules of the House allows, is but another instance of the diminishing power of the private member and the increasing domination of the Government. Lord George Hamilton stated last week that he had asked the Universities of Oxford, Cambridge and London to nominate representatives on the Board of Visitors. When reconstituted the Board is to appoint a committee to hold an inquiry into the whole working of the College. This committee can do nothing to lessen the gravity of the recent action of the Board of Visitors in the matter of the dismissed teachers. They may, however, be able to secure some sort of recognition of the professoriate in the management and policy of the College, and some diminution of the absolute power of one individual, which has recently wrought such harm both at Coopers Hill in England and at the Leland Stanford University in America.

THE reality of the connection between rats and plague is prominently brought into notice by the issue of a circular by the Local Government Board, instructing the sanitary authorities of seaports to take precautions against the entrance of plague-infected rats into this country. On the arrival in port of a vessel upon which, during the voyage, plague or sickness suspected to be plague has occurred, measures are to be taken to secure the destruction of the rats on board the vessel, and to prevent them from reaching the shore. In the case of vessels that have come from places infected with plague, strict inquiry is to be made on their arrival in port as to mortality or sickness among rats during the voyage. In the event of rats on board any ship being found to be infected with plague, all parts of the vessel frequented by those animals are, so far as possible, to be disinfected. The authorities of seaport towns invaded by plague are advised to endeavour to secure the destruction of the rats in the town, not least those inhabiting the docks and quayside warehouses. In connection with these instructions, it is worth while to bear in mind that plague is not usually transmitted by the bite of a diseased rat, but by fleas living on such rats. Experiments have shown that a healthy rat will quickly contract plague if caged with a diseased rat infested with fleas, but will not do so if the diseased rat is free from fleas. Perfectly healthy rats harbour very few fleas and are very expert in removing them, but these insects are abundant on sick rats. After death, as the body becomes cold, the fleas leave the rat, and if they reach another rat or human being they may inoculate their new host with the bacilli of plague.

PROF. BROUARDEL, Dean of the Paris Faculty of Medicine, has announced that at the end of his present term of office—namely, in February 1902—he will not accept re-appointment.

THE Rev. James Chalmers, who is reported to have been murdered in New Guinea, with the Rev. O. F. Tomkins and twelve students, was known to many anthropologists, and made some noteworthy contributions to our knowledge of the natives of New Guinea, where he passed twenty-three years of his life. His death has often been reported before now, and there is always a possibility that rumours from New Guinea will prove to be untrue; but we fear that in this case the news will be confirmed.

THE founders' medal of the Royal Geographical Society has been awarded to the Duke of the Abruzzi for his expedition to Mount St. Elias and for Arctic exploration. Dr. A. Donaldson Smith has been awarded the patrons' medal for his African expeditions and the important scientific observations made in connection with them. Awards have also been made to Mr. Louis Bernacchi and Captain Colbech for their aid in the *Southern Cross* Antarctic expedition, and to Captain Cagni for his journey to 86° 33′ N., on the Duke of the Abruzzi's expedition.

WE are reminded by the *British Medical Journal* that on October 13 Prof. Rudolf Virchow will complete his 80th year, and preparations are already being made by his numerous friends and pupils to celebrate that interesting anniversary with appropriate pomp and circumstance. A committee has been formed for the purpose of collecting subscriptions, to be applied to the development of the Rudolf Virchow Stiftung, which was established for the furtherance of science in 1881. The president of the committee is Prof. Waldeyer, the distinguished anatomist of Berlin; the secretary is Prof. Posner.

THE committee appointed by the International Congress of Geologists in August last has, says *Science*, announced as the subject proposed for the Spendiaroff prize for 1903 "A Critical Review of the Methods of Classification of Rocks" (Revue critique des méthodes de classification des roches). The value of the prize is 456 roubles, or about 64*l*. Manuscripts should be addressed to M. Charles Barrois, secrétaire général du Congrès Géologique International, 62, Boulevard Saint Michel, Paris. At least two copies of papers submitted in competition are required, and they should be sent, at the latest, a year before the next session of the Congress in 1903.

THE erection of a memorial to the late Prof. Huxley in Ealing, where he was born and received his early education, is contemplated. On the initiative of the council of the Ealing Natural Science Society, a committee of those persons connected with the district who are interested in the project has been formed. The first meeting of this committee was held on March 29, when an executive committee was appointed with the Rev. Prof. G. Henslow as chairman. A bronze medallion portrait has been advocated for the central feature of the design, which may take the form of a simple mural tablet or of a more worthy monument, as funds are obtainable, while should that support be forthcoming for which its projectors hope, an annual grant or medal might also be founded. Subscription to the fund is not confined to residents in Ealing, and persons who may be desirous of assisting in the endeavour to show honour to the memory of Huxley in the place of his birth should communicate with the treasurer of the fund (Mr. T. Simpson, Fennymere, Castle Bar, Ealing), or with the secretary (Mr. B. B. Woodward, 120 The Grove, Ealing).

THE investigation of the Louisiana Gulf Coast, made by Prof. Beyer for the American Ornithological Association for the purpose of stationing wardens to protect the sea birds, shows that action was not taken a moment too soon. Prof. Beyer found that nearly all the breeding places of the birds had been destroyed by killing the birds themselves and taking their eggs. Not a trace of birds was found on either Brush or Caillou Islands, at one time the home of millions of sea fowl. The same was true of Calumet and Castelle Islands, on which every living thing had been killed. A few gulls and hens were found left on Timbalier Island, and there are said to be a few on Last Island, which, however, could not be visited on account of the severe weather. Wardens were appointed wherever birds were found, and the fishermen of the neighbourhood promised to co-operate with the wardens in preventing the killing of the birds in the breeding season and the stealing of eggs.

THE annual general meeting of the Zoological Society was held on Monday. In the report of the council, reference was made to the publication of the fifteenth volume of the Society's *Transactions*, consisting of a monograph of the genus Casuarius, by the Hon. Walter Rothschild. A new pheasantry was built during the past year, and is now tenanted by a full series of members of the pheasant family. The number of visitors to the Gardens in 1900 was 697,178, showing a slight increase over the corresponding number in the previous year. The number of animals living in the Society's Gardens at the end of December last was 2865, of which 758 were mammals, 1495 birds, and 612 reptiles and batrachians. Amongst the additions made during the past year thirty-one were specially commented upon as being of remarkable interest, and in most cases new to the Society's collection. The Duke of Bedford was re-elected president of the Society.

WE learn from the *Electrician* that, in response to the complaints of a number of leading shipping companies, including the White Star, Cunard and American Lines, the Board of Trade has instructed the Marconi Company to erect a signalling station on the mainland close to the Fastnet Rock, at the western extremity of Ireland. All vessels fitted with wireless transmitting apparatus will henceforth be able to report to the shore when many miles outside the Fastnet, and this will, of course, abolish the waste of time and labour caused by the necessity for incoming steamers to pass inside the Fastnet in order to report to Lloyd's station on the mainland.

THE deposits of salt at Salton, California, U.S.A., forms one of the sights of America. They occur in a depressed portion of the Colorado Desert, parts of which are as much as three hundred feet below sea-level. The deposits cover as much as a thousand acres, and the company in possession of the area has shipped from it annually about two thousand tons of salt. The salt is cut by means of a plough and is piled into heaps such as those shown in the accompanying illustration, reproduced from the *Scientific American*. Each plough harvests about seven hundred tons of salt per day. A singular characteristic of the bed is that the salt is being deposited daily by springs which run into the basin, and as the water evaporates it leaves behind a crust of almost pure sodium chloride, which ranges from ten to twenty inches in thickness over the area. Geographers will remember that the deposits occupy part of the area of the desert of California flooded to the extent of hundreds of square miles in 1892, when the Colorado River broke it barriers.

THE origin of coal and the extent to which the coalfields of Great Britain have been worked were the scientific questions dealt with by Mr. E. B. Wethered in his presidential address to the Cotteswold Naturalists' Field Club on April 23. It was pointed out that the extent of our present exportation of coal was not contemplated by the Royal Coal Commission in 1871. In 1867 the amount of coal exported was 10,233,135 tons, and it was thought that no considerable increase would take place, whereas nearly fifty-six million tons were exported in the year 1899, including about twelve million tons consumed by steamers engaged in foreign trade. In the matter of home consumption the Commissioners were remarkably correct, their estimate for 1899 being 162,400,000 tons, the actual figures being 164,284,757 tons. Mr. Wethered suggests that another Commission should be appointed to consider the probable duration of the coalfields. Another point on which information is required is as to what natural stores of coal are under the Secondary rocks, and at what depths. It is of national importance that this information should be obtained.

Symons's Meteorological Magazine for April contains what purports to be the first tables of the climate of Pemba ever published. They were taken by Mr. T. Burtt at Banani, during the years 1899 and 1900. The small island of Pemba forms, with Zanzibar, that portion of the British East Africa Protectorate nominally under the rule of the Sultan of Zanzibar, the position of Banani being approximately 5° 15′ S., 39° 43′ E. The temperature is of course very uniform, the mean of the monthly maxima being 83°·4 and of the minima 70°·8, the absolute maximum being 95° and the minimum 65°. The rainfall is copious, averaging about 98 inches. The two rainy seasons are well marked, the greater being March to May, and the less November to January.

MR. G. W. KIRKALDY has favoured us with a copy of his paper on the stridulating organs of water-bugs, recently published in the *Journal* of the Quekett Microscopical Club. The males of these insects, which alone produce the sounds, can mostly be referred to their proper species from the stridulating organs alone. Generally it seems that the sound is produced by drawing the comb-like structure situated on the tarsus of one leg across the femur of the other, and *vice versâ*. But it is believed that there is also a second musical area, one of the constituents, at least, of which is situated on the abdomen. Observations are needed as to the precise *modus operandi* of both types of stridulating organs in these insects.

THE *Biologisches Centralblatt* of April 1 contains the two concluding sections of Dr. C. Rengel's account of the life-history of the great black water-beetle commonly known as *Hydrophilus piceus*. It is shown that, unlike those of the brown water-beetles (*Dytiscus*), which devour free-swimming creatures like tadpoles and the larvæ of other insects, the larvæ of the black water-beetle subsists on slow-moving organisms, especially pond-snails. In the earlier stages of their existence the larvæ devote their attention to Physa and the smaller kinds of Lymnæa, but when full grown they do not hesitate to attack the comparatively large *Planorbis corneus*. The idea that these larvæ always seek a hole in the ground in which to pupate is shown to be incorrect, the transformation having been observed to take place among a mass of weeds. It seems also that when a hole is selected, this is not excavated by the larvæ themselves. By an inadvertence the title of this paper occurs in the table of contents of the *Centralblatt* of April 15.

THE issue of the *Revue Scientifique* of April 20 contains the first instalment of an interesting article by M. Henri Coupin on the song of birds. The author commences by referring to the large proportion of tuneful species met with among the birds of Europe, which he sets at ten per cent., whereas in the tropics it falls as low as one per thousand. The gorgeous birds of the tropics he compares to actresses without talent, who depend for success on the richness of their toilets. Stress is then laid on the fact that, in spite of its simplicity, bird-song cannot be imitated by any known musical instruments. It is possible, indeed, to reproduce the pitch and intensity of the notes, but not the *timbre*, which includes such a multitude of sounds as to defy imitation. Indeed, the observations of M. F. Lescuyer have shown that although the notes of birds correspond to those of our musical scale, yet they also include a number of vibrations occupying the intervals between our notes, and it is this which renders imitation impossible. In most birds the duration of the song is very brief; in the thrush and the chaffinch it lasts only two or three seconds, in the blackcap from four to five seconds, and from two to five minutes in the lark. The author then proceeds to analyse the sounds constituting the songs of birds, and to distinguish between their songs and their alarm-cries.

WE have just received Part vii. of the bibliography of the more important contributions to American economic entomology, issued by the U.S. Department of Agriculture (Division of Entomology), extending from December 31, 1896, to January 1, 1900. This part, prepared under the direction of Prof. L. O. Howard, the entomologist, by his assistant, Mr. Nathan Banks, contains an alphabetical index, under authors' names, of 1383 papers in different American periodicals, and a subject-index extending to thirteen pages (double columns) in small type. The book is a good illustration of the energy with which economic entomology is pursued in the United States, where, however, it must be remembered that insects are much more numerous and destructive than in Europe, or at least in England.

THE issue of *Die Umschau* for April 20 contains a short illustrated article on the ship *Gauss*, which has been built for the German Antarctic Expedition. A photograph from a model and some views of the vessel in various stages of construction are reproduced.

DR. E. FRIEDRICH contributes a paper on the india-rubber production of Africa to the *Deutsche geographische Blätter*. The export statistics of twenty-five African colonies are dealt with, and the results exhibited graphically on a sketch-map, from which some interesting geographical conclusions are drawn.

THE *Verhandlungen* of the Berlin *Gesellschaft für Erdkunde* contain a brief abstract of a lecture, by Dr. K. Kretschmer, on the physical development of the North Sea coasts during historic times. The author refers specially to the regions near the mouths of the rivers Ems and Jade, and describes changes recorded by various authorities since Roman times.

WITH reference to Mr. T. W. Kingsmill's letter in last week's issue (p. 608), Prof. Haddon writes to say that he appreciates its value, but at the same time he wishes to disclaim any first-hand knowledge of Chinese authorities, and to remark that in his article he merely gave an account of M. Ujfalvy's views.

A VOLUME on the history of physiology during the sixteenth, seventeenth and eighteenth centuries, by Sir Michael Foster, will shortly be published in the Cambridge University Press Biological Series, edited by Mr. A. E. Shipley. The book will consist of lectures delivered by the author last autumn before the Cooper Medical College in San Francisco. Without claiming to be a complete history of the subject the book will contain a full account of the chief advances made in physiology from the time of Vesalius until the beginning of the nineteenth century. In the same series Prof. Marshall Ward is issuing a work on grasses on a somewhat novel plan. It is essentially a practical book, to be used in the field and in the laboratory, and should be of use, not only to the botanist, but also to the farmer and the gardener.

WE have received from Messrs. A. E. Staley and Co. a catalogue of microscopes manufactured by the well-known Bausch and Lomb Optical Co. of Rochester, New York, U.S.A. From the description of their works contained in the catalogue it is evident that the method of production is essentially American. Machine tools of the most modern description and specialisation of the manufacture of component parts should result in every article being of the highest class. The instruments listed of the so-called "Continental" type do not call for special notice. Of the cheap stands, the American type microscope (F.) is undoubtedly of good design. The horse-shoe foot is replaced by one of a much more stable tripod form, and the arm carrying the tubes and adjustments is particularly well made, giving freedom all round the stage while securing a firm support for the body-tube. All the usual microscope accessories are listed, but there is nothing of such special design as to call for particular notice.

THE additions to the Zoological Society's Gardens during the past week include two Wild Swine (*Sus scrofa*, ♂ ♀), European, presented by H.M. the King; a Leopard (*Felis pardus*) from West Africa, presented by Captain Guy Burrows; an Eland (*Orias canna*, ♂) from South Africa, presented by the Duke of Bedford; two Grey-breasted Parrakeets (*Myopsittacus monachus*) from Monte Video, presented by Mrs. Brownrigg; two Ground Snakes (*Typhlops exocoeti*) from Christmas Island, presented by Sir John Murray, K.C.B., F.R.S.; a Grey-cheeked Mangabey (*Cercocebus albigena*) from West Africa, a Brazilian Tree Porcupine (*Sphingurus prehensilis*) from South America, two Black Tortoises (*Testudo nigra*) from the Galapagos Islands, three Dark Green Snakes (*Zamenis gemonensis*), two Smooth Snakes (*Coronella austriaca*), European, deposited; a Sambur Deer (*Cervus aristotelis*, ♂) from India, two Javan Peafowls (*Pavo spicifer*, ♂ ♀) from Java, two Peacock Pheasants (*Polyplectron chinquis*, ♂ ♀) from British Burmah, two Australian Sacred Ibises (*Ibis strictipennis*) from Australia, two Summer Ducks (*Æx sponsa* ♂ ♀) from North America, two Blood-breasted Pigeons (*Phlogaenas luzonica*) from the Philippine Islands, four Ruffs (*Machetes pugnax*, ♂ ♂, ♀ ♀), twelve Green Lizards (*Lacerta viridis*), European, purchased.

OUR ASTRONOMICAL COLUMN.

COMET a (1901).—The Sydney correspondent of the *Times* reports that a brilliant comet was seen early on Tuesday morning (April 23) at various stations throughout the Australian continent. It was stated to have been near the star Aldebaran (α Tauri).

On Friday, the 26th ult., a telegram received from Dr. Gill announced that the new comet had been observed from the Cape Observatory. It was very brilliant, having a compound triple tail about 10° long. The comet was observed on the eastern horizon some two hours before sunrise and was rapidly approaching the sun, so that it may be expected to become more brilliant as perihelion is passed. It was seen by the observers at the Yerkes Observatory at Wisconsin early on Saturday morning last, about 15° north of the sun. This indicated that it had made a very rapid north-westerly movement in relation to its position when seen at the Cape. It was visible for fully twenty minutes before sunrise and about fifteen minutes after, and is considered the brightest comet seen for the last nineteen years. No account has yet been received of the comet having been seen in this country.

THE APRIL METEORS OF 1901.

A SERIES of very clear nights enabled these objects to be looked for in favourable circumstances this year. Moreover, the moon was absent, so that the smaller class of meteors could be well seen projected on the dark blue of the cloudless sky. Meteors are usually very rare in April, and it is only the shower of Lyrids, occurring in past years on about the 20th, that has made the month interesting to meteoric observers. The display apparently returns annually, but it is often inconspicuous and rarely proves as rich as the August Perseids.

On April 13, 17, 18 and 19 I maintained a watch of the north-east region of sky, but found meteors scarce and there were very few Lyrids. The minor showers of the epoch gave little sign of their presence; in fact, meteoric apparitions were so few and far between that observers found their patience sorely tested. Prof. Herschel watched perseveringly at Slough on the nights of April 10, 13, 14, 15, 16 and 17, and, in the aggregate, only recorded twenty meteors in 8½ hours.

On April 20 at Bristol the sky was brilliantly clear, and I kept a look-out during about five hours of the period from 9h. 50m. to 15h. 30m, but observed only twenty-nine meteors. Not a single Lyrid was included amongst them, though several bright, swift-moving meteors fell from a bordering radiant at 261° + 36° in Hercules.

On April 21 the firmament was less favourable, but soon after commencing to watch at 9h. 45m. I found meteors extremely numerous. Several of the minor showers were very active, and the Lyrids formed a pretty rich display. During 3¼ hours' watching, up to 14h. (allowing for occasional interruptions by clouds), I counted fifty-two meteors, and of these there were twenty-five Lyrids from a radiant about 5 degrees in diameter with 270° + 33° as a centre. But while registering the observed paths of the meteors seen, many others must have eluded detection. The horary rate of meteoric apparitions for a continuous watch of the firmament by one observer would have been about 25 and the proportion of Lyrids 12. The figures represent rather an unusual display, though falling far short of the strength of the Perseids and some other periodical showers. It must be remembered, however, that at the epoch of the Lyrids meteors are generally very rare, and that the principal shower is itself sometimes very feeble, if not quite invisible.

The fact of the maximum being so definitely marked on April 21, while there was a comparative absence of Lyrids on April 19 and 20, shows that for some time in future we must expect these meteors on the former date. This is, no doubt, owing to 1900 not having been a leap year. And the shower appears to be a very fugitive, short-lived one, or it must have exhibited more decided traces on April 19 and 20. Though I saw no Lyrids whatever at Bristol on April 20, Prof. Herschel informs me that he observed 5 during the night.

Nearly all the Lyrids seen this year were accompanied with streaks; this feature was, indeed, as well shown as it usually is in the case of the Perseids, Orionids and Leonids. When the radiant was rather low on April 21, the apparent motions were estimated as slow and slowish; but in the later hours of the night, with increasing altitude of the radiant, the velocity appeared much swifter.

Some of the meteors from Lyra and other constellations were very interesting, and in the following list I have made a few selections in the hope that the objects may have been observed elsewhere, and that the requisite data may be obtained for computing their real paths in the air.

	h.	m.	Mag.	From °	°	To °	°	
April 21 ...	10	9	♃ ...	278½	+52 ...	304	+70	Lyrid
	10	41	3 ...	202	+40 ...	213½	+ 7	α-β Perseid
	10	50	2 ...	210	+50 ...	171	+40	Lyrid
	10	59	2 ...	218	+52 ...	255	+75	Virginid
	11	23	1 ...	70	+57 ...	88	+50	Cassiopeid
	12	47	2 ...	269	+46 ...	305	+49	Virginid
	13	7	♃ ...	242	+74 ...	130	+74	Lyrid

On April 20, at 10h. 35m., I noticed a brilliant double flash, caused probably by a large meteor at a low altitude, and hidden from my view by houses in this locality.

Two meteors appearing on April 18 were mutually observed at Slough and Bristol. The first was seen at 13h. 19m., and it fell from an altitude of 83 to 55 miles over Oxfordshire. The radiant was at 266° + 33°, so the meteor was an early Lyrid, and it having been well seen at both stations, the direction of its flight was recorded with considerable accuracy. The position of its radiant at 266° + 33°, as compared with the general Lyrid centre at 270° + 33° three nights later, on April 21, proves that this shower, like that of the August Perseids, exhibits a radiant moving eastwards at the rate of about one degree per day. The second meteor doubly observed was registered at 14h. 47m., and it descended from 58 to 44 miles over the borders of Gloucestershire and Oxfordshire. The radiant was at 247° ± 0°, so the meteor belonged to one of the minor showers of the epoch.

Since writing the above I have learnt that two bright meteors, the 1st and 5th in the above list, were observed by Mr. C. L. Brook at Meltham, near Huddersfield, as well as at Bristol. The first was a Lyrid with radiant at 268° + 30°, and it fell from 79 to 54 miles in height over the Midlands. Its length of path was 60 miles and velocity 40 miles per second. The other meteor was a Cassiopeid belonging to a radiant at 21° + 59°, and falling from 66 to 44 miles over Merioneth and Cardigan, Wales. Its observed length of path was 55 miles and velocity 14 miles per second. It is remarkable that though few, if any, of the smaller class of shooting stars diverge from this radiant near δ Cassiopeiæ in the spring months it yet furnishes many fireballs. In the General Catalogue of Radiants, No. xv. p. 228, the radiants of five fireballs appearing in April and May give a mean centre at $20° + 57°$, which is almost identical with that of the bolide of April 21 last. W. F. Denning.

CHEMISTRY IN ITS RELATIONS TO ENGINEERING.[1]

The engineer of fifty years ago can hardly be said to have received any special educational training; he forced himself to the front in virtue of his qualities and industry alone. But the youth who to-day intends to become an engineer feels it wise, if not necessary, to decide where he shall receive, not only his general, but also his engineering education. While he was at school he will have learnt much about the simpler and more general laws and facts of mechanics and natural science, both by description and by practical work in the laboratory and in the workshop; he will also have attained to some proficiency in mathematics, in one or more of the modern languages, in drawing and in other usual school subjects. When he passes on to his college career his knowledge of these subjects will undergo expansion in the class-room and especially in the laboratory and workshop. It is satisfactory to find that many of our leading schools for training engineers exist in connection with institutions in which pure and applied mathematics, natural science and modern languages are efficiently taught even in their higher stages. The engineering student is thus afforded the opportunity of following up the higher study of any one of these subjects, if his taste and energy lead him to wish him to do so. But even his ordinary course of instruction always includes the opportunity of obtaining lecture and laboratory instruction in chemistry.

Chemistry in Engineering Education.

It appears to be the general feeling of those who have had experience in teaching chemistry to engineering students that it is useless to attempt very much in the small amount of time which can be allotted to the subject in the regular curriculum; it is evidently felt, however, that a student who wishes to attain to any considerable proficiency in the subject should be encouraged to join certain additional courses which are included in the ordinary chemical curriculum.

Probably all that can be expected of the average engineering student is that he shall become generally conversant, during his college course, with chemical language, with chemical principles and laws, and with the chemical nature of the materials with which he has to deal; and that he should obtain such an insight into chemical analysis as to be able to confer with the trained chemist, and to understand the meaning of a general statement of the results of chemical analyses bearing on metals, alloys, fuel, lubricants, cements and other materials which are frequently used by the engineer.

It is beyond question that the engineer has too many calls upon his time and energy, both in his training and in his subsequent career, to allow of his becoming a chemist or a chemical analyst; but he should at least be sufficiently conversant with the science to enable him to appreciate the important bearings of chemistry on his varied requirements, and to enable him to avail himself intelligently of the results of chemical investigation and analysis. He should be able to watch and to appreciate any chemical inquiry and investigation, even if he is not qualified to suggest its methods of procedure or to carry it out himself.

It has been stated to me by a German manager of large English works, who has frequently occasion to call in the professional advice and assistance of both engineers and chemists, and who is himself well educated in both departments, that he has to lament in this country the "absence of useful engineering knowledge among chemists, and of useful chemical knowledge among engineers." Another informant states that Germany employs many more trained chemists working in conjunction with her engineers than England does.

Applications of Chemistry to Engineering.

In order to illustrate some of the advantages which engineers have derived from chemical coadjutors, one or two instances may be selected from different fields of engineering activity and enterprise.

In the matter of supplying the engineer with suitable constructive materials, the most striking case is that of the introduction of cheap steel of varying qualities in substitution for costly steel and other less suitable forms of iron.

The Bessemer process owed its original suggestion, as well as its salvation from failure, to the chemical knowledge which was supplied to those who were interested in the procedure. It further owed the extension of its application to all the commonest, cheapest and most abundant kinds of impure English cast iron to the further utilisation of chemical knowledge and suggestion.

At the present time the metallurgical chemist and the chemical metallurgist are engaged in furnishing metals and alloys, new to commerce, which can rank in importance with cheap steel, only in a somewhat minor degree; and the engineer in every department of his activity is now continually having placed at his disposal alloys which are more suitable for his various designs than any which he has hitherto employed.

It is scarcely necessary to point out the absolute necessity of chemical knowledge and chemical advice to the gas engineer. In the matter of water supply, also, both the engineer and the chemist find their respective but closely connected spheres of duty.

There is another direction in which the constant relation of chemistry to engineering, and in which the association of the chemist with the engineer must be maintained, if success is to be secured and expensive failures are to be avoided.

In no application of chemical and engineering principles is the co-operation of chemist and engineer more necessary for the attainment of success than in securing the suitable purification of our town sewage. Such co-operation has enabled London, Manchester and other large centres of population in recent years to carry out on an experimental scale most important trials of the natural or bacterial treatment of sewage, and has led to reports on this method being published which will probably become classical. This experimental work has led to considerable and valuable development and improvement of the bacterial method. There is now no doubt that this process can inexpensively dispose of a large proportion of the putrescible sediment or sewage-sludge, and can render the effluent, not only non-putrescible and suitable for maintaining the life of fish, but even pure if necessary. The process is therefore destined to effect great reforms in our sewage-disposal problem and considerable improvements in the condition of our watercourses.

[1] Abstract of the "James Forrest" lecture delivered at the Institution of Civil Engineers on April 25 by Prof. Frank Clowes.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The Rede Lecturer for the present year is Dr. F. W. Maitland, Downing professor of law. Dr. Haddon, F.R.S., gives this term a course of lectures on studies in Papuan ethnology and the races of Oceania, on Mondays and Fridays at 2.30 p.m.

The Medical School Buildings Syndicate recommend the acceptance of tenders for the erection of the Downing Street wing and the Humphry Museum, amounting to more than 26,000*l.*

The Frank Smart studentship in botany at Caius College, of the annual value of 100*l.*, will be vacant at Michaelmas. Candidates must have taken honours in Part i. of the Natural Sciences Tripos. Further information may be had from the senior tutor of the College.

A meeting was held in St. John's College on April 27 for the purpose of procuring a portrait of Prof. Liveing, F.R.S., as a memorial of his lifelong services to the University. The meeting was largely attended by members of the Senate, and a warm tribute was paid to the professor, who began his teaching of chemistry fifty years ago, and who during that time has in many ways, public and private, benefited the University, town, and county of Cambridge. A strong committee was formed to carry out the purpose of the meeting.

Prof. Newton announces that there are vacancies for workers at the University tables in the Plymouth and the Naples zoological stations. Applications are to be sent to him by May 23.

Twenty-one candidates have passed the half-yearly examination in sanitary science for the diploma in Public Health, held in April.

Dr. J. N. Langley, F.R.S., is re-appointed deputy-professor of physiology until Michaelmas 1903, in the place of Sir M. Foster, M.P.

MR. R. T. SMITH has been appointed principal of the Northern Polytechnic Institute. He organised and equipped the South African College, Capetown, and acted as professor of mathematics and physics in the College for several years; and, more recently, was lecturer in mathematics and physics in the Goldsmiths' Institute, New Cross.

THE Secretary of State for War has appointed a committee to consider the education of candidates for commissions in the Army and the system of training at Woolwich and Sandhurst, and to report whether any changes are desirable in the present methods of entrance into the Army. The following will form the committee:—The Right Hon. A. Akers-Douglas, M.P. (chairman); the Rev. Dr. Warre, headmaster of Eton; Mr. F. W. Walker, high master of St. Paul's School, Hammersmith; Colonel Jelf, C.M.G., Royal Engineers; Lieutenant-Colonel Hammersley, Lancashire Fusiliers; Captain Lee, M.P., late professor of strategy and tactics, Royal Military College, Canada; and Captain W. E. Cairnes, Royal Irish Fusiliers (secretary).

ADVOCATES of improvements in geometrical teaching will be glad to know that the Civil Service Commission has lately introduced a change of importance to all who are concerned with Civil Service examinations. Before this year an instruction at the head of examination papers in geometry stated that "Proofs other than Euclid's must not violate Euclid's sequence of propositions." Upon recent papers, however, this has been superseded by the note that "Correct demonstrations, whether those of Euclid or not, will be accepted." It thus becomes possible for teachers preparing pupils for the Civil Service to be independent of Euclid's sequence or proofs. Recent questions also encourage teaching of a less abstract character than that usually associated with Euclid's geometry. We understand that the Board of Education will accept alternative proofs of propositions in future examinations in geometry.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, April 26.—Dr. R. T. Glazebrook, foreign secretary, in the chair.—A paper on the thermodynamical correction of the gas thermometer was read by Prof. H. L. Callendar. This paper commences by giving a short historical sketch of the thermodynamic correction of the gas thermometer, describing some of the solutions to Thomson's fundamental equation for the Joule-Thomson plug experiment. The assumptions made in the solutions have sometimes been erroneous and wrong corrections have been obtained. From 1885 to 1888 Chappuis made a series of careful comparisons between various gas thermometers and a very delicate mercury thermometer, and drew up a table of differences between the hydrogen and the nitrogen thermometer. The author has taken the observations of Chappuis and calculated a new table of differences. The index "n" in the modified Joule-Thomson equation is not constant. For steam it is about 3·5 and for carbonic acid about 2. The thermodynamic correction is very small, especially in the case of hydrogen and helium, and is very much less than the correction for the expansion of the thermometer bulb. Prof. Herschell asked whether the co-volume came into the correction. Dr. Harker looked forward to the experiments which Prof. Callendar proposes to make with a constant pressure thermometer. The chairman expressed his interest in the extreme delicacy of the observations of Chappuis.—A paper on the production of a bright-line spectrum by anomalous dispersion and its application, the "flash-spectrum," by R. W. Wood, was read and experimentally illustrated by Mr. Watson. It has been suggested by W. H. Julius that the "flash-spectrum seen immediately at totality may be due to photosphere light abnormally refracted in the atmosphere of metallic vapours surrounding the sun. The light which will be thus abnormally refracted will be of wave-lengths almost identical with the wave-lengths which the metallic vapours are themselves capable of radiating. The sun is supposed to be surrounded by an atmosphere of metallic vapours, the refractive index of which decreases with increasing distance from the surface. In this atmosphere the rays of light coming from the photosphere move in curved paths. The refractive index is, however, very small, except for wave-lengths very near those absorbed by the vapour, consequently the light which resembles that emitted by the vapours, is most strongly refracted, and therefore curves sufficiently to reach us after the photosphere has been hidden by the moon. The flash-spectrum of sodium was shown by focussing the light of an arc lamp on a horizontal slit in front of a flat metal plate supported so that the plane in which its under-surface lay coincided with the plane of the slit. At a distance of about two metres a direct vision spectroscope was arranged to give a vertical spectrum and placed at such a height that the prism barely caught the rays coming from the slit and grazing the plate. On looking into the spectroscope a bright continuous spectrum is seen. A Bunsen burner was then placed underneath the metal plate and fed with sodium. This produced a layer of sodium vapour of varying refractive index. On raising or lowering the spectroscope bright sodium lines are seen due to anomalous dispersion. By arranging screens these lines can be obtained so that, on cutting out the arc lamp, the flash-spectrum vanishes. Prof. Herschel expressed his interest in the experiments and their application to the case of the flash-spectrum seen at totality.

PARIS.

Academy of Sciences, April 22.—M. Fouqué in the chair.—On the residues and periods of double integrals of rational functions, by M. Émile Picard.—On an apparatus designed to move the photographic plate which received the image furnished by a siderostat, by M. G. Lippman. In an image given by a siderostat only one point is really fixed, the other points appearing to move round this with a variable velocity. It is shown that a suitable motion can be given to the photographic plate capable of overcoming this defect by means of a gear driven by the clockwork of the siderostat.—On the existence of nitrides, argonides, arsenides and iodides in crystalline rocks, by M. Armand Gautier. The finely powdered granites and basalts were decomposed by heating at 100° with phosphoric acid. Determinations are given of the amount of nitrogen, arsenic and iodine in various rocks.—Comparison of the work done by a muscle in sustaining and lifting a charge, by M. A. Chauveau.—On the propagation of discontinuities in a viscous fluid; extension of the law of Hugoniot, by M. P. Duhem.—On a question relating to a displacement of a figure of invariable size, by M. R. Bricard.—On entire functions of several variables and their modes of growth, by M. Émile Borel.—Some isotherms of ether between 100° and 206°, by M. Edouard Mack. The pressure of the ether vapour was balanced by a piston floating on a very viscous liquid, and the volume of the ether, which was completely surrounded by a mercury bath, was deduced from the motion of the piston.—Cryoscopic researches, by M. Paul Chroustchoff. An account of some of the precautions necessary in applying the platinum thermometer to the measurement of the lowering of the freezing-point of dilute solutions.—On a new system of ammeters and voltmeters independent of the intensity of their permanent magnets, by M. Pierre Weiss. In an instrument of the d'Arsonval type a decrease in the strength of the permanent magnet causes a decrease in the sensibility of the instrument; in instruments having a movable magnetic needle controlled by a permanent magnet the opposite is the case. If, in an instrument of the moving coil type, the coil carries a small piece of soft iron, these two effects may be made self-compensating. It was found possible to construct a galvanometer of this type in which the sensibility was practically invariable.—On the influence of self-induction upon spark spectra, by Mr. G. A. Hemsalech. Three photographs are given showing the progressive changes produced in the spark spectra of cobalt, lead and magnesium by an alteration in the self-induction of the spark circuit.—Periodic oscillations productions by the superposition of an alternating current on a continuous current in an electric arc, by M. E. Kœnig.—On an apparatus which imitates the effect of luminous fountains, by M. G. Trouvé.—On barium hydride, by M. Guntz. Barium hydride, the existence of which was first indicated by Winkler, has been obtained in a pure state and found to have the composition BaH_2. This compound is of remarkable stability; it can be slowly sublimed in a current of hydrogen at 1400° C. without decomposition. Heated in a current of nitrogen, barium nitride is formed.—The estimation of nitric acid in waters by means of stannous chloride, by M. H. Henriet. The fact discovered by Divers and Haga that nitrates react with stannous chloride giving hydroxylamine chloride has been applied by the author to the quantitative determination of nitrates in potable waters.—The action of various alcohols upon some acetals of monovalent alcohols, by M. Marcel Delépine. — On three new alkaloids from tobacco, by MM. Amé Pictet and A. Rotschy. Further particulars of the physical and chemical properties of the three alkaloids nicoteine, nicotimine and nicotelline.—The action of phenylhydrazine and of hydrazine upon the two isomeric methyl butyrylacetylacetates, by M. Bongert. On paraoxyhydratropic acid, by M. J. Bougault.—Some new reactions of organometallic derivatives, by M. E. E. Blaise.—On a new base derived from glucose, by MM. L. Maquenne and E. Roux. The base, which is termed glucamine, is obtained by reducing glucosoxime with sodium amalgam.—Action of the alkylcyanacetic esters on the diazochlorides, by M. G. Favrel.—Reduction of the nitro-derivatives of the azoic colouring matters, by M. A. Rosenstiehl.—On two new acetylenic acids. Synthesis of caprylic and pelargonic acids, by MM. Ch. Moureu and R. Delange.—On the indoxylic origin of certain red colouring matters of urine, by M. L. Maillard.—The calculation of the results of milk analyses, by MM. Louise and Riquier.—Segmentation in the genus Trochus, by M. A. Robert.—Action of isotonic solutions of chlorides and of sugar on the eggs of *Rana fusca*, by Mme. Ronfeau-Luzeau.—The stimulation of nerve and muscle by waves of very short duration, by M. G. Weiss.—Action of alcohol upon the gastric secretion, by MM. Albert Frouin and M. Molinier. The increased secretion of the gastric juice caused by alcohol is shown experimentally not to be due, as has been usually supposed, to a direct local action, nor is it due to an effect produced upon the nerves of taste.—On the second fermentation of the wines of Champagne, by M. E. Manceau.—Apparatus for the exact measurement of the skeleton and of other organs giving a clear image in radiography, by M. G. Contremoulins.—On the origin and mode of formation of the Oolitic iron ore of Lorraine, by M. Stanislaus Meunier.

DIARY OF SOCIETIES.

THURSDAY, May 2.

Royal Society, at 4.30.—On the Variation in Gradation of a Developed Photographic Image when impressed by Monochromatic Light of Different Wave Lengths: Sir W. de W. Abney, F.R.S.—Ellipsoidal Harmonic Analysis: Prof. G. H. Darwin, F.R.S.—On the Small Vertical Movements of a Stone laid on the Surface of the Ground: Horace Darwin.—On the Intimate Structure of Crystals. Part V. Cubic Crystals with Octahedral Cleavage; Prof. W. J. Sollas, F.R.S.

Linnean Society, at 8.—Studies in Heterogenesis: Prof. H. C. Bastian, F.R.S.

Chemical Society, at 8.—The Synthetical Formation of Bridged-Rings. Part I. Some Derivatives of Bicyclopentane: Prof. W. H. Perkin, jun., F.R.S., and Dr. J. F. Thorpe.—Ballot for the Election of Fellows.

Institution of Electrical Engineers, at 8.—An Instrument for Measuring the Permeability of Iron and Steel: C. G. Lamb and Miles Walker.—A Watt-Hour Meter: Frank Holden.

Röntgen Society, at 8.—Some X-Ray Improvements: James Cadett.

FRIDAY, May 3.

Royal Institution, at 9.—Memory: C. Mercier.

Society of Arts, at 8.—Polyphase Electric Working: A. C. Eborall.

Anatomical Society, at 4.—(*a*) Additional Notes on the Articulations between the Occipital Bone, Atlas, and Axis in the Mammalia: (*b*) On the Development of Digits in Cetacea; (*c*) Observations on the Development of the Human Brain before and after Birth: Prof. Symington.—A Contribution to the Study of the Morphology of Adipose Tissue: Dr. H. Batty Shaw.—A Lantern Demonstration showing the Origin and Nature of the Hydatiform Bodies of the Testicle and Broad Ligament, with Special Reference to the Fate of the Mullerian Duct in the Epididymis: J. H. Watson.—Relation of Structure to Function, as illustrated by the Growth of the Inferior Femoral Epiphysis: Prof. Arthur Thomson.

Geologists' Association, at 8.—Geology and the Growth of London: A. Morley Davies.

SATURDAY, May 4.

Royal Institution, at 3.—Climate: its Causes and its Effects: J. Y. Buchanan, F.R.S.

MONDAY, May 6.

Society of Arts, at 8.—Alloys: Sir W. C. Roberts-Austen, K.C.B., F.R.S.

TUESDAY, May 7.

Royal Institution, at 3.—Cellular Physiology: Dr. A. Macfadyen.

Society of Arts, at 4.30.—The Coal Problem—its Relations to the Empire: Lieut. Carlyon W. Bellairs, R.N.

Zoological Society, at 8.30.—On the Spiders of the Family Attidæ found in Jamaica: Mr. G. W. Peckham and Mrs. E. G. Peckham.—On the Hymenoptera collected during the "Skeat Expedition" to the Malay Peninsula, 1899–1900: P. Cameron.—On the Arachnida collected during the "Skeat Expedition" to the Malay Peninsula, 1899–1900: M. Eug. Simon.

WEDNESDAY, May 8.

Society of Arts, at 8.—School Work in Relation to Business: Sir Joshua Fitch.

Geological Society, at 8.—The Influence of the Winds upon Climate during the Pleistocene Epoch: a Palæo-Meteorological Explanation of some Geological Problems: F. W. Harmer.

Iron and Steel Institute, at 10.30.—Annual Meeting.

THURSDAY, May 9.

Royal Society, at 4.30.

Mathematical Society, at 5.30.—(1) A Case of Algebraic Partitionment; (2) On the Series whose Terms are the Cubes and Higher Powers of the Binomial Coefficients: Major MacMahon, R.A., F.R.S.—A Property of Recurring Series: G. B. Mathews, F.R.S.—The Product of Two Spherical Surface Harmonic Functions: J. B. Dale.

Institution of Electrical Engineers, at 8.—Storage Batteries in Electric Power Stations, controlled by Reversible Boosters: J. S. Highfield.

Iron and Steel Institute, at 10.30.—Annual Meeting.

FRIDAY, May 10.

Royal Institution, at 9.—The Response of Inorganic Matter to Mechanical and Electrical Stimulus: Prof. J. C. Bose.

Society of Arts, at 8.—Polyphase Electric Working: Alfred C. Eborall.

Royal Astronomical Society, at 8.

Malacological Society, at 8.

SATURDAY, May 11.

Royal Institution, at 3.—The Rise of Civilisation in Egypt: Prof. W. M. Flinders Petrie.

CONTENTS.

THURSDAY, MAY 9, 1901.

EARLY HISTORY OF THE THERMOMETER.

Evolution of the Thermometer, 1592–1743. By Henry Carrington Bolton. Pp. 98. (Easton, Pa., U.S.A.: Chemical Publishing Co., 1900.) Price 1 dollar.

THIS is a most interesting little book, giving the history of the thermometer from the time of Galileo to that of Celsius and Christin.

Galileo's first instrument is thus described in a letter written by Father Castelli and dated 20th September, 1638, in which he says it was used in public lectures 35 years before. "Galileo took a glass vessel about the size of a hen's egg, fitted to a tube the width of a straw and about two spans long; he heated the glass bulb in his hands and turned the glass upside down so that the tube dipped in water held in another vessel; as soon as the ball cooled down the water rose in the tube to the height of a span above the level in the vessel; this instrument he used to investigate degrees of heat and cold."

According to Viviani, author of a "Life of Galileo," published in 1718, this instrument was invented about the time he became professor of mathematics in Padua; this was towards the end of 1592.

Sanctorius, a medical colleague of Galileo, appears to have appreciated the value of fixed points for graduation, and for this purpose he used snow and the heat of a candle; the range thus obtained he divided into degrees. The thermometer was applied by him to take the temperature of the human body; in one instrument the bulb was constructed so as to go into the patient's mouth.

Sanctorius, in his "Commentaries on Galen," speaks of the thermometer "as a most ancient instrument," and it has been suggested by Cleveland Abbe that the instrument was known before the time of Galileo and that his work consisted in the addition of a scale.

The first sealed thermometer was made some time prior to 1654 by Ferdinand II., Grand Duke of Tuscany; he filled the bulb and part of the tube with alcohol, and then sealed the tube by melting the glass tip. Ferdinand and his brother, Leopold de Medici, promoted the establishment in Florence of the Accademia del Cimento, and the accounts of their experiments, published in 1667 and translated into English by Waller in 1684, contain descriptions of various thermometers made and used by the members. One of these old thermometers was given by the Grand Duke of Tuscany to the late Prof. Babbage, and is now in the Cavendish Laboratory at Cambridge.

In England about the same time Boyle made experiments on thermometers. His "Lectures on Cold" were published in 1665 in obedience to the command of the Royal Society, "imposed on me in such a way that I thought it would less misbecome me to obey it unskilfully than not at all. Especially since from so illustrious a company (where I have the happiness not to be hated) I may, in my endeavours to obey and serve them, hope to find my failings both pardoned and made occasions of discovering the truths I aimed at."

The second discourse of these lectures contains some "New Observations about the Deficiencies of Weather Glasses, together with some considerations touching the New or Hermetical Thermometers."

Boyle felt the need of fixed points. Hooke, in his "Micrographia," describes some thermometers with stems above four feet long, in which the range between summer and winter was nearly the length of the stem. To graduate the stems he placed zero at the point where the liquid stood when the bulb was in freezing distilled water; thus to him belongs the credit of taking the temperature of the freezing point of water as the lower fixed point.

There appears to be considerable doubt as to who first employed mercury as the thermometric liquid; the Accademia del Cimento used such an instrument in 1657, and they were known in Paris in 1659. Fahrenheit, however, appears to have been the first to construct, in 1714, mercury thermometers having trustworthy scales.

The use of the boiling point of water as the upper fixed point was suggested by Carlo Renaldini in 1694, who published, at the age of eighty years, a work on natural philosophy.

Sir Isaac Newton, in his "Scala Graduorum," published in the *Phil. Trans.* in 1701, adopts linseed oil as the thermometric liquid. He took as the fixed points the melting point of ice and the temperature of the human body, calling the one 0° and the other 12°. On this scale he gives as the boiling point of water 34°, and as the melting point of lead 96°. Newton did not adopt the boiling point of water as a fixed point.

After an interesting reference to Amontons and others who worked at thermometry in the latter part of the seventeenth century, Mr. Bolton describes the labours of Fahrenheit, who was born in 1686. His work began in 1706. His skill as a glass worker was very great and enabled him to carry out many designs. In his own account of the instrument he says: "The scale of the thermometers used for meteorological observations begins below with 0° and ends with 96°. The division of the scale depends upon three fixed points, which are obtained in the following manner. The first point below at the beginning of the scale was found by a mixture of ice water and sal ammoniac or also sea salt; when a thermometer is put in such a mixture the liquid falls until it reaches a point designated as zero . . . . The second point is obtained when water and ice are mixed without the salts named; when a thermometer is put into this mixture the liquid stands at 32°, and this I call the commencement of freezing . . . . The third point is at 96°. The alcohol"—it is expressly stated earlier that the thermometers were of two kinds, the one containing alcohol, the other mercury—"expands to this height when the thermometer is placed in the mouth or in the armpit of a healthy man and held there until it acquires the temperature of the body."

Above this temperature the scale was merely lengthened by dividing the tube into equal spaces; one of the divisions marked 212° on a certain thermometer was observed to coincide with the boiling point of water, thus the division of the fundamental interval between the freezing point and boiling point into 180 parts was accidental. If we take these two temperatures as our points of departure, marking them as 32° and 212°, the normal temperature of the human body is 98°·4, not 96°

as on Fahrenheit's original scale, so that the scale now known by his name differs slightly from that originally defined by him. Two of his original instruments are in the Physical Laboratory at Leyden; the freezing points as now given by them are at 34°·2 and 34°·1 respectively; both of these are mercury thermometers.

After Fahrenheit's time came various imitators, each with his own special scale; for an account of them we must refer the reader to Mr. Bolton's pages. Among them the scales of Réaumur and of Celsius alone survive, though, as Mr. Bolton points out, Celsius proposed to call the boiling point of water 0° and its freezing point 100°; the change to the present centigrade scale was made independently in 1743 by Christin, of Lyons, and seven years later by Strömer, a colleague of Celsius at Upsala.

Réaumur's choice of 80° for the temperature of steam was made as a result of his experiments on the expansion of alcohol. He found that alcohol, diluted with one-fifth water, expanded in volume from 1000 to 1080 when raised from the freezing point to the boiling point.

Mr. Bolton is to be congratulated on his work. He has made it most interesting, and it deserves many readers; it suggests the hope that some one may take up similarly the history of other physical instruments and write about them in as bright and capable a manner.

THE OXFORD TEXT-BOOK OF ZOOLOGY.

A Treatise on Zoology. Edited by E. Ray Lankester Part II. *The Porifera and Coelentera.* By E. A. Minchin, G. H. Fowler and G. C. Bourne. With an introduction by E. Ray Lankester. Pp. x + 405. (London: Adam and Charles Black, 1900.)

THE second part of the "Treatise on Zoology," now appearing under the editorship of Prof. Ray Lankester, contains six chapters, the work of four different authors, graduates of the University of Oxford. An introductory chapter by the editor, on the Enterocœla and Cœlomocœla, deals with the main divisions of the Metazoa; Prof. E. A. Minchin writes on the Sponges; Dr. G. H. Fowler on Hydromedusæ and Scyphomedusæ; and Mr. G. C. Bourne on the Anthozoa and Ctenophora. The high character of the whole work, of which the volume previously published (Part III. Echinoderma) gave promise, is fully established by that now before us, and it can scarcely be doubted that this treatise will, for some time to come, be regarded as the standard English text-book for advanced students of zoology.

The classification of the Metazoa adopted by Prof. Lankester in the introductory chapter is based upon the work of the most recent writers on animal morphology, and differs in several ways from that previously adopted in the text-books. The whole animal kingdom having first been divided into two grades, the Protozoa and the Metazoa, the grade Metazoa is considered as giving rise to two branches, the Parazoa, or Sponges, and the Enterozoa, the latter name being a term previously introduced by Prof. Lankester as a substitute for Haeckel's term Metazoa, but which he now proposes to restrict to the second great division of the Metazoa. The view thus adopted of the position of Sponges in the animal kingdom is that advocated by Minchin in the present work (see p. 158); but, as that author points out, it is one which is by no means accepted, at the present time, by other leading authorities on the morphology of the Porifera.

After this main division of the Metazoa, Prof. Lankester proceeds to divide the Enterozoa into two branches, the Enterocœla, or those in which the sole cavity is the enteron, and the Cœlomocœla, those in which the cœlom is present as an independent second cavity. It is certainly open to doubt whether any advantage is gained by the introduction, in a work of this character, of these new terms to replace the already so widely used Cœlentera (or Cœlenterata) and Cœlomata. Indeed, Prof. Lankester himself appears to regard his new nomenclature as tentatively put forward for the consideration of his fellow morphologists, for it is not even adopted in the present volume. The title-page bears the name Cœlentera, and this is the term used both by Mr. Bourne and Dr. Fowler in their sections of the work, the latter writer making use also of the form Cœlenterata (p. 60), to which the editor of the treatise takes exception.

The remaining portion of the introductory chapter gives, in a clear and interesting manner, an account of the author's views with regard to the cœlom and its relations to the other cavities of the body in the different phyla of the Cœlomata (Cœlomocœla), together with a detailed history of the progress of our knowledge of that organ. The discussion of this subject is noteworthy on account of the particularly clear statement of the author's theory of the body-cavity relations found in the Mollusca and Arthropoda. According to this theory, now termed the theory of Phlebœdesis, the true cœlom is present in these groups in a reduced form, whilst the blood-holding spaces (hæmocœl) are in reality swollen blood-vessels. In support of this view, Benham's work on *Magelona* (*Quart. Journ. Micr. Sci.*, xxxix. 1896) is brought forward. The concluding part of the chapter is of interest from the great importance attached to the recent work of Meyer and of Goodrich on the nephridia and cœlomoducts of the marine Chætopoda, the views of these authors being entirely adopted, notwithstanding the fact that they revolutionise the prevailing ideas on the subject, ideas which owe their origin very largely to Prof. Lankester himself.

Prof. Minchin's section on the Sponges, we have little hesitation in saying, contains the most successful account of an animal group which has yet appeared in this treatise. It is in many ways a model of what such a general account should be, and is certainly the most satisfactory summary of our knowledge of the Porifera which at present exists in any language. It is by no means merely a compilation and discussion of facts already put on record by other authors. Much new matter is here recorded for the first time—notably the account of the development of *Clathrina blanca*—and a large part of the descriptive portions of the chapter is the direct outcome of the author's own observation and experience. Prof. Minchin's work as a histologist, which has shown him to be an expert in the most recent and delicate methods of technique, is well known, but the present article proves him to be at the same time a painstaking and observant outdoor naturalist. That a sponge is a living organism and that each species is specially adapted to the particular set of natural conditions under which it grows are facts which are seldom absent from his mind, and as a consequence there is a freshness and reality about much which he has written that are often absent from the writings of the laboratory and museum worker.

Dr. Fowler's accounts of the Hydromedusæ and Scyphomedusæ are, in our opinion, the least satisfactory portions of the volume. The style is too concentrated and concise to make the writing effective, and intellectual interest has been entirely sacrificed in an attempt to introduce every available fact and to deposit it in a properly labelled compartment. The result resembles the syllabus of an advanced course of lectures on the groups dealt with rather than an intelligible account of those groups.

In the chapters on Anthozoa and Ctenophora, Mr. Bourne presents us with an excellent series of detailed descriptions of particular types, together with a clearly stated and well-marshalled body of facts concerning the groups as a whole. His work will undoubtedly prove of great value to both teachers and students. We, however, fail to find in these two sections that originality of treatment and originality of thought which characterise Prof. Minchin's section on the Porifera.

The whole work is well illustrated, being in this respect a great improvement on the volume of the treatise previously published (Part III. Echinoderma). The figures for which Prof. Minchin and Mr. Bourne are responsible, many of which are original, are specially worthy of praise.

THE GRAPHICAL MENSURATION OF VAULTS.

Il Calcolo Grafico applicato alla Misura delle Volte. Prof. Ernesto Breglia. 5th serie, vol. i. (Atti del Reale Istituto d'Incoraggiamento di Napoli, 1899.)

GRAPHICAL methods are used to a certain extent in the solution of engineering problems, although perhaps their employment is not so extended as their neatness and simplicity merit. In some cases, it is true, where the simplification is great and the application easy, they are used practically to the exclusion of other methods. But in other cases where a graphical treatment would effect almost as great a simplification the methods have never been very generally applied. The reason lies, we think, in the fact that it requires greater ingenuity to treat a problem graphically than analytically. Problems such as occur in practice, even though they may be complicated, can generally be hammered out by analytical means. A good mathematician, no doubt, will be able to find a short cut to the solution, but the engineer, whose ready stock of mathematical knowledge on which he can draw with ease amounts to little more than the algebra he learnt at school and an acquaintance with the principles of the calculus, will be able to work out the solution by dint of determined plodding. With graphical methods it is different. To begin with, the geometrical training which an English engineer receives at school is a hindrance rather than a help, so that when he comes to study graphical systems he finds himself in a region unknown to him and is obliged to disembarrass himself of the Euclidean notions acquired in his youth. We are afraid that the Englishman will never be quite happy in using geometrical methods until the groundwork of his knowledge is laid with some more suitable text-book than Euclid's Elements. In addition to this, with these methods each new problem requires somewhat different treatment; it is hard, and often impossible, to lay down very definitely the lines on which to proceed. The ingenuity which is consequently required can only be obtained, by any except the born mathematician, by the habitual use of the system.

Prof. E. Breglia's paper illustrates what we have been saying. The method that he has worked out for measuring the volumes of arches and vaults is extremely neat. In the simpler cases it is, as is natural, very much easier to follow and apply, and the ease of doing so is such that it should commend itself to all who have need to make such measurements. In the cases of vaults of more complicated shape the method becomes also more complex; artifices have to be used in order to "dodge" the more important difficulties. It is just these artifices that are so difficult to find when a new problem is attacked. To apply Prof. Breglia's method to the determination of the volume of a vault similar in shape to one of those he has examined in the paper before us would be fairly simple, even though the shape might be very complicated; to apply it to the case of a vault of quite a different shape would not be nearly so easy. Prof. Breglia has, however, examined a great variety of cases in a thorough manner, and has thus rendered his paper very valuable.

Prof. Breglia's system has other advantages besides a simplicity which enables the volume of a vault of complicated shape to be found without the use of advanced mathematics. The accuracy can be increased practically at will by varying the number of sections into which the vault is divided; with analytical methods high accuracy is often only attainable by undue complication of the mathematics. We are inclined to think, also, with Prof. Breglia that error is less likely to occur in its use, as should any mistake be made it will show itself directly; but this is an advantage that must not be given too great weight, as graphical methods possess possibilities of error, especially in the interpretation of the results, which are not to be met with in other methods. The system is, however, a very useful one, and the paper is worthy the careful attention of all those interested in the subject.

OUR BOOK SHELF.

Experimental Chemistry. By Lyman C. Newell, Ph.D. Pp. xv + 410. (Boston: Heath and Co., 1900.) Price 5s.

DR. NEWELL has added one more to the already formidable array of elementary science text-books, each of which, according to their respective authors, has been written to supply a long-felt need. In the present instance, the object is to promote the more efficient teaching of chemistry by modern methods; and in writing his book Dr. Newell has been actuated by "a desire to provide a course of study which shall be a judicious combination of the inductive and deductive methods."

We fail to see in what way Dr. Newell's book superior to a hundred others of a similar kind. The ideal that the author has set before him is a very high one, and we should be the last to deprecate any attempts to improve upon modern methods of teaching experimental science. It is obvious that the time at the disposal of the average student is so limited that it would be quite impossible to carry out the logical method consistently, and at the same time cover any but the most elementary parts of the subject; the only question is as to the nature of the compromise.

Dr. Newell has attempted to cover a very wide field, with the result that a large amount of matter has been inserted which is beyond the range of an elementary student and of little use to the more advanced. His method is one that is excellent in theory, but in practice easy to carry to excess. To the title of a treatise on elementary chemistry the book lays no claim; it is nothing more than a guide-book for use in the laboratory, and must be supplemented by others for detailed information; while as a work of educational value it is by no means the most efficient that could be devised. Elementary students, however, will doubtless find portions of it of considerable assistance, for the experiments are carefully described, and the illustrations clear.

The Elements of Darwinism, a Primer. By A. J. Ogilvy. Pp. 160. (London: Jarrold and Sons, 1901.) Price 2*s*. 6*d*.

THE object of this little book is, as the author states in the preface, to give the ordinary non-expert reader an intelligent notion of the theory of natural selection. There is no doubt that there is scope for such a work, for even at the present time it is remarkable how widespread are the ignorance and misapprehension of Darwin's teaching among the general public. Mr. Ogilvy divides the subject into three parts: general statement, consisting of eleven chapters; illustrations, consisting of seven chapters; and a third part consisting of nine chapters. Although keeping fairly well within the limits of Darwin's teaching, the author shows some originality of treatment, and has not slavishly followed the custom so prevalent at one time of simply rearranging the facts collected by our great master and dishing them up as an original contribution to science. Several new illustrations of Darwinian principles are introduced, some of them appropriate and forcible, others less appropriate and in some cases altogether questionable. In the chapter on flight, for example, the author attempts to define two kinds: "Now some birds fly chiefly by muscular, some by nervous power." The condor and the albatross are quoted as examples of the former, and the partridge as an example of the latter. The principles which have governed the author in classifying the contents of the various chapters are not in all cases clear, and a rearrangement might have been made in some instances with advantage. One other very obvious defect is the too facile exposition of evolutionary steps which are at present difficult to understand, and of which the course is confessedly obscure. The kind of reader for whom Mr. Ogilvy has written his book is just the person upon whom such treatment would produce an impression of dogmatic security. In spite of these defects, however, any one previously ignorant of the subject who carefully reads the volume cannot fail to acquire a fairly sound idea of Darwinism, and this is all that the author claims to have had in view. It should be added that the manuscript has been read by Dr. Alfred Russel Wallace, who does not, however, hold himself responsible for all the statements. R. M.

La Betterave à Sucre. Par L. Malpeaux. Pp. 206. (Paris: Mayson and Gauthier-Villars. No date.) Price fr. 2.50.

THIS small volume, one of the series known as "l'Encyclopédie scientifique des Aide-Mémoire," is prefaced by a few general considerations upon the importance of the sugar beet. In the opening chapter the history and the present state of cultivation, as well as the future of the sugar beet, are dealt with. As regards the future it is interesting to note that as the supply already meets or even exceeds the demand, the only hope held out to the cultivator is an increase in the consumption of sugar. The second chapter treats shortly of the production of sugar in the plant. A brief description of the different varieties of beet is followed by a chapter on the production of seed. This is perhaps the most interesting portion of the volume before us. In it the methods of selection, physical, chemical and genealogical, the culture of seed plants and the analysis of the roots are given at some length. Then follow chapters on the influence of climate and soil and manures. The important fact that the beet removes from the soil very little else than carbon, hydrogen and oxygen, and therefore the manures supplied to it benefit the crops which follow, is duly insisted on. Two short chapters on sowing, hoeing and thinning are followed by one on diseases, insect and other pests. Although a number of remedies, such as sprinkling with copper arsenite, &c., are mentioned, proper cultivation is upheld as the most important factor in preventing and overcoming such diseases and insect ravages. The remaining pages are devoted to the harvesting and storage, the marketing, and, in connection therewith, the analysis of the juice and the cost of cultivation.

The illustrations are clearly drawn and the curves showing annual production of roots, &c., are a valuable feature of the book. A bibliography of the subject, in which French authors only are mentioned, is attached. The addition of an index would add to the value of this useful monograph. J. E. M.

Assimiliation chlorophylienne et la Structure des Plantes. By Dr. Ed. Griffon. Pp. 106. (Paris: Georges Carré et C. Naud.) Price 2 francs.

L'Evolution du Pigment. By Dr. G. Bohn. Pp. 96. (Same publishers.) Price 2 francs.

THESE two manuals belong to the biological section of the valuable "Scientia" series, each volume of which contains authoritative descriptions of subjects in which progress is being made.

Dr. Griffon's brochure deals with a subject which has engaged the attention of many physiological botanists. Numerous determinations have been made of the physicochemical properties of chlorophyll; and the experimental methods employed to measure the changes resulting from the action of its functions have been so much improved in recent years that valuable results are frequently obtained. But there is a matter which has almost been left in the background, namely, the influence of the structure of plants on the decomposition of carbon dioxide. It is true that important data have been obtained upon this subject, but they are chiefly from special points of view, and no general conclusions have been reached. Dr. Griffon reviews the work which has been done upon this subject, both as regards plants which naturally differ among themselves in anatomical characters and plants of the same species of which the structural differences are due to varying conditions as regards light, heat, hygrometric state, presence of various mineral salts, &c. A chapter upon the nature and measurement of assimilation in plants precedes this treatment, and one on the principal factors determining the rate at which carbon dioxide is decomposed concludes the book. Dr. Griffon succeeds in presenting a connected account of researches and results of interest to all students of botany.

Dr. Bohn's book opens with a general statement of cell structure, bacteria and pigmentary bodies. He then deals in succession with the constitution and biology of pigments, modifications of pigment in organisms, evolution of pigment in various groups of animals, and utilisation of colour in nature for protective and other purposes.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Scope of the Royal Society.

As a general principle it is not desirable to make the affairs of the Royal Society a subject of public discussion. The question to be submitted to the consideration of the fellows on May 9 is, however, of sufficient general interest to justify an exception.

The notice given has been short, and I am unable to be present. No vote is to be taken. It will, therefore, not be too late to draw attention to some facts which appear to me to have been overlooked.

The starting point of the matter as it is presented to the Society is contained in the following statement:—

"The Society exists for the promotion of Natural Knowledge. The interpretation of the term 'Natural Knowledge,' according to the present practice of the Royal Society, assigns to it a range from Mathematics to the various Biological sciences, and this secures the inclusion of the scientific study of man in his biological relations. It has been argued that this range might be properly increased by the inclusion of the scientific study of man in his reasoning, social and historical relations. It may, indeed, be further contended that the Society should include in its scope all branches of Natural Knowledge which are capable of consecutive and ordered development. Such a test would permit the inclusion of subjects such as Psychology, Economics, Historical Science and Philology in the widest sense of the term, which, under the present practice of the Society, may be deemed excluded, but which, when pursued as they now are by the most capable students, in a scientific spirit and by scientific methods, do fall within the domain of Natural Knowledge. The investigation, for instance, of the phenomena of the origin and variations of human speech, of the beliefs and customs of primitive man, of the production and distribution of wealth, of the laws which govern the development of political societies, is an investigation into natural phenomena in a sense which the progress made in our conceptions of nature during the last two centuries seems to justify."

Now I have always understood—and my impression is confirmed by the highest authority—that admission to the Society is actually open to any one who has promoted Natural Knowledge, in whatever field, by scientific methods. The open door may not have been taken advantage of, but I am not aware that there is the smallest ground for believing that it has ever been closed. What I wish to draw attention to is that though the actual representation of the subjects enumerated above may not have been as full as it might have been, I am unable to agree that they, "under the present practice of the Society, may be deemed excluded." A rather cursory inspection of the names of those who have been fellows, or have been elected during the last twenty years, confirms my opinion. Under Economics I find Heywood, Newmarch, Sir James Caird, Jevons, Palgrave, Sir Robert Giffen, Charles Booth and Shaw-Lefevre. I am under the impression that for the period this is a very fair, if not actually adequate, representation of economic science. Historical Science, I presume, must be taken to include archæology and ethnography, otherwise these will have again to be "deemed excluded." Assuming that this is not so, I find the names of General Pitt-Rivers, Sir Augustus Franks, Canon Greenwell, Tylor, Penrose and, in the list now recommended by the Council, of Arthur Evans. Of Historians, in a restricted sense, I find Dean Stanley and Sir Henry Howorth, and, if Privy Councillors are included, of Bryce and John Morley. And with regard to the class of Privy Councillors, it is to be remarked that although any one is eligible it is apparently rare for any to be elected without something more than mere political qualifications. Philology has been more weakly represented; still, I find the names of the Dean of Canterbury, Alexander Ellis, Sir Henry Rawlinson and Bryan Hodgson. And if Psychology finds its only representative at the moment in Lloyd Morgan, it is, I believe, an open secret that Herbert Spencer might, had he thought fit, have been a fellow of the Society.

Besides the names I have enumerated, I am very much disposed to doubt if a score can be enumerated, or perhaps even half that number, of others in the same fields who during the last twenty years possessed conspicuous claims to admission to the Society. Nor can I believe that if men like the late Bishops of Oxford and London or Freeman had been willing to become candidates there would have been any likelihood of their being unsuccessful. Like Thorold Rogers, whom I often urged to allow himself to be proposed, they may not have desired admission. W. T. THISELTON-DYER.

Kew, May 6.

The Spectra of Carbon Monoxide and Silicon Compounds.

A PAPER published by Prof. Hartley (*Proc.* Roy. Soc. vol. lxviii. pp. 109-112, March, 1901) reminds me of some observations on the spectra of the compounds of silicon with fluorine and hydrogen ($SiFl_4$ and SiH_4), made by me several years ago and published in *Wiedemann's Annalen* (vol. xxi. pp. 427-437, 1884). As they seem to be not without some interest, and a definite explanation of them has, so far as I know, not been given till now, I may be permitted to give here a short account of the principal contents of my little paper.

A vacuum tube filled with $SiFl_4$ and procured from Geissler Nachfolger, in Bonn, showed a spectrum of which the greatest part consisted in the well-developed band spectrum due to carbonic oxide, besides which there appeared the eight beautiful blue lines, or rather stripes, that seemed (at least then) to be characteristic of $SiFl_4$. Now there is nothing wonderful about the presence of traces of the carbonic oxide spectrum in a vacuum tube, as is well known, but in our case it was so predominant, as if one had not simply to deal with impurities, but on the contrary, as if it was the principal part of the phenomenon. Intending to clear up the circumstances, I tried to prepare vacuum tubes from which the presence of carbonaceous matter, as well as of air and moisture, were as much as possible excluded, and finally the $SiFl_4$ gas was developed from a mixture of pure glass and flourspar powder and also purest sulphuric acid in an apparatus composed entirely of glass and sealed directly to a Toepler mercurial pump. All stop cocks and sliding pieces that want greasing were totally avoided. Nevertheless, the carbonic oxide spectrum remained in its very predominant position; at low pressures it was even present almost alone, as if one were working on a carbonic oxide tube containing some impurities due to silicon combinations. Sometimes, it is true, the carbonic oxide bands were less brilliant, and the blue stripes (belonging to $SiFl_4$?) more prevailing, from what cause I do not know, but still the carbonic oxide spectrum always remained well visible. Perhaps it is worth mentioning that sometimes there were seen four additional lines situated more towards the violet end of the spectrum, and occasionally, also, some green ones. Also the well-known swan spectrum could be obtained, especially when the discharges of a Leyden jar were sent through the vacuum tube. Even tubes illuminated in the well-known manner without the use of electrodes still showed the carbonic oxide spectrum in its predominant position. If some traces of oxygen had been developed from moisture, which, as is well known, it is almost impossible to totally remove from the glass apparatus used, and this had, by combining with some carbonaceous compound present in the tube given rise to some traces of carbonic oxide, then one could, so far as I know, only have expected a rather faint spectrum due to it. I do not know if the suggestion of carbon being contained in the element silicon is at all acceptable, according to present knowledge, but at all events the brilliant appearance of the CO bands awaits, as I believe, a sufficient explanation.

In a rather high vacuum this CO spectrum is not seen, but there are visible (except lines due to mercury, hydrogen, &c.) some lines also observable in highly exhausted tubes filled with carbonaceous compounds, but which, as I found in the latter case, only appear when luminous points are seen at the electrodes and the glass covers that partially surround them. As I found those lines to coincide with lines observed in the spark spectrum of $SiFl_4$ at high pressures, this so-called vacuum spectrum probably belongs to some silicious matter evolved out of the above-mentioned glass covers by the action of the said bright points.

Under suitable conditions SiH_4 also showed the carbonic oxide and swan spectrum, and as well the one ascribed to hydrogen, this latter especially being seen at lower pressures, whilst of a silicon spectrum nothing was observable. Only at higher pressures, by the aid of spark discharges, some of the lines were obtained that had been seen formerly in the spark spectrum of $SiFl_4$.

As my principal object in these researches had only been to get rid of the carbon spectrum (though in vain), I did not make any measurements of wave-length. Later on, as many laboratories were provided with powerful spectroscopic apparatus, I did not believe it to be any longer worth while to work on the subject with small instruments, hoping some other investigator would take care of it. I should be very glad if the present note would induce some spectroscopist to control and further pursue my observations. In addition, some researches with very strong sparks seem to me to be very desirable.

Berlin. KARL V. WESENDONK.

The Dust of "Blood-Rain."

I HAVE handed to Prof. Judd the specimens of "blood-rain" dust collected by me in Sicily, as mentioned in your issue of March 28. It may be remembered that the dust was collected from three tables on the terrace of the hotel, and that I brought home that from the most favourably situated table in the wet state in which it was obtained. This has since been dried and weighed, with the result that, as I expected, the density of the fall was greatest on this table, being equivalent to $9\frac{1}{4}$ tons per square mile. The average given by the other two tables was $5\frac{1}{2}$ tons per square mile.

The largest value is probably the best, but if we take the mean we shall be within the mark in saying that the density of the fall near the theatre at Taormina was about 7 tons to the square mile. ARTHUR W. RÜCKER.

A Convenient Primary Cell.

IN your "Notes" of April 18 (p. 594) you give an account of the new cell—the Cupron-element—brought out by the Accumulator Industries Company. Without intending any disparagement, will you allow me to point out that the cell, with the exception of the special form of copper oxide for which the company justly claim credit, was invented long ago by Lalande, but does not appear to be known so widely as its merits deserve. I have used the cell for a considerable time, the positive plate taking the form of a plate of copper faced on one side with granular copper oxide held in its place by a piece of copper gauze, and can corroborate the statements as to its very low resistance and great constancy. For elementary work, where resistances of a few hundredths of an ohm are to be compared and a galvanometer of negligible resistance used, I have found it most valuable. Another form of the cell, in which the copper plate is merely painted with a mixture of copper oxide powder and gum and then heated until the latter chars, is very readily set up, but has a rather greater internal resistance. Where this is desirable it may be regulated within considerable limits by making the cell a "sawdust Lalande," which has obvious advantages on other grounds. A. E. MUNBY.

Felsted.

THROUGH the kindness of the Editor I am able to reply to Mr. Munby's interesting letter. I did not intend by my note to imply that the "Cupron-element" was an entirely new combination, and indeed suggested that its chief claim to novelty lay in the construction of the copper oxide plate. The Accumulator Industries, Ltd., it is only fair to say, fully acknowledge in their circular that the cell is developed from the copper oxide element of Lalande and Chaperon. It is interesting to have Mr. Munby's testimony to the convenience of the cell, which is, I believe, used to a considerable extent on the Continent, but, as your correspondent says, is not very widely known in England.

THE WRITER OF THE NOTE.

AGRICULTURAL SEEDS.

UNDER the auspices of the Board of Agriculture a committee was appointed last summer to take into consideration the conditions under which agricultural seeds are at present sold, and to report whether any further measures can, with advantage, be taken to secure the maintenance of adequate standards of purity and germinating power.

The committee met on ten occasions and examined upwards of thirty witnesses, seed-merchants, farmers and scientific witnesses, including Mr Carruthers, Mr. Gilchrist, Mr. Hall, Profs. T. Johnson, McAlpine and Somerville. The evidence of these witnesses is now published as a Blue-book, whilst the report of the committee is issued separately.

Taking the report first, the committee find that there is [now] no wide-spread complaint of the quality of seeds sold throughout the country. The committee, further, think that every encouragement should be given to seed-merchants to give a guarantee with the seeds they sell, and that farmers should be advised to buy only subject to such guarantee and to test the seeds they have purchased. To facilitate this the committee recommend the establishment of one central seed-testing station under Government auspices, with the aid and counsel of a small committee of experts. The report is signed by all the members of the committee. Two of their number, Sir W. T. Thiselton-Dyer and Mr. Leonard G. Sutton, while agreeing generally with the findings of the committee, raise objections to the proposal to establish a Government seed-testing station.

It is satisfactory to hear that the general quality of the seeds sold has greatly improved of late years. This improvement is, no doubt, in great measure due to the passing of the Adulteration of Seeds Act, an Act, it may be pointed out, which was promoted by the seedsmen themselves, who desired to purify their business from seed-killing, seed-dyeing and other questionable practices which had been allowed to grow up to such an extent that it was difficult for a merchant to avoid conniving at, if not practising them.

At present, so far as the large firms are concerned, there is in general no question as to the excellence of the seeds they sell, and those who, like the writer of the present notice, have had the opportunity of witnessing the care taken in selecting the seed and in afterwards cleaning it and preparing it for market will corroborate this statement. With the smaller dealers, especially in some parts of Wales and Ireland, the case seems different. There the farmers often buy relatively small quantities of seeds of low quality and equally low price from local tradesmen, ironmongers, cornfactors and the like, who have no other knowledge of seeds than such as is necessary for securing the best means of disposing of them. It is especially for the protection of small, and often ignorant, farmers that the seed-testing station is intended.

All the large firms test their own seeds and the seeds they buy from the Continent or elsewhere. Moreover, they grow them in their own trial grounds. They do this on a very much larger scale than would be possible in a seed-testing station.

Some of the smaller firms, and perhaps some of the large houses also, occasionally make use of the seed-control stations at Zurich or Halle, and they find it a grievance that they have to send to Switzerland or Germany for information which obviously could as well be obtained here. Indeed, the botanists of the Royal Agricultural Society (Mr. Carruthers) and of the Highland and Agricultural Society of Scotland (Mr. McAlpine), and perhaps others, do undertake to test seeds for the members of their several societies, or, under certain conditions, for outsiders.

These tests, wherever they be made, have reference to the "purity" of the seed, its germinating power and its "genuineness." By purity is meant freedom from seeds of weeds or other admixtures. The germinating power is tested by the percentage of seeds in any given sample which, under favourable conditions, is found to produce healthy seedlings. Theoretically a hundred per cent. should grow. In practice the percentage may, without fault of the seedsman, be, in certain cases, much below this, but it is satisfactory indeed when one thinks of the many contingencies to which the clover plant is subjected to find it to be quite common for 98 per cent. of the seed to grow. When one thinks of the humble bees, and the mice and the cats and the vicissitudes of the climate, it seems remarkable that such a percentage of good seed should ever be obtained.

What seedsmen mean by the "genuineness" is another matter, but one of extreme importance. It would be quite impossible even for an expert to recognise seed of a particular stock or breed, say of broccoli or turnip. There are good stocks and bad "stocks" of these, but they cannot be distinguished by their seeds. A mere seed-testing station, private or official, could render no assistance in such cases. The only way to test the genuineness of a stock is to grow it and watch it throughout the season. Obviously the purchaser could not wait for that, he must trust to the good faith and reputation of the seedsman.

Considering, then, the vast scale on which seed-testing and seed-trials are now made by the leading firms and the limited scale on which seeds can be tested at a seed-testing station, and, further, bearing in mind that the ordinary seed-trials give no indication of "genuineness," we do not see that the farmer for his immediate practical purposes would be materially benefited by a seed-testing station. It would answer his purpose very much better to devote a little care to testing the seeds for himself from a sample procured some weeks before he required to sow for a crop. The seedsman, in his turn, should give a guarantee that the bulk should be equal, or closely approximate, to the sample. We say closely approximate because so numerous and so varied are the vicissitudes to which the seed is, or may be, exposed that some latitude, say to 5 or even 10 per cent., would only be reasonable.

Farmers in general sow much too thickly, so that a lower percentage than is theoretically desirable might well be condoned in practice if the seed were good of its kind.

While saying so much we are far from wishing to undervalue the importance of research-stations wherein the phenomena of germination as well as other physiological and pathological processes might be studied from the point of view of research. Associated with a small trial-ground, such stations would be very valuable for the investigation of the properties and mode of life, not only of old well-known crops, but also of new introductions. It is just here that the value of the "crank of a scientific man" would show itself. One of the witnesses objected to placing such a man at the head of a Government seed-testing station because "they get so infallible and then they take notions in their heads."

It is as well to see ourselves as others see us. We should have thought infallibility in this connection was a sign of nescience rather than of science.

MAXWELL T. MASTERS.

THE MARINE RESOURCES OF THE BRITISH WEST INDIES.

THE above is the title of a paper by Dr. J. E. Duerden, which, with a series of appendices, has lately been issued as an extra number of the *West Indian Bulletin*—the official journal of the Imperial Agricultural Department of the West Indies. As read, it formed the leading feature of a recent Congress at Barbados, held under the auspices of the aforenamed Department, at which representatives of all the West Indian Islands were present, and it sets forth in a concise and connected form the essence of all that has transpired in the utilisation for economic purposes of the rich resources of the West Indian seas. In the first part of the paper the fisheries of Jamaica, the Barbados, Bahamas, Leeward Islands, Trinidad, St. Vincent, British Guiana and Honduras are each dealt with in turn, mainly from the statistical standpoint; and then, in descending zoological order, there are treated the principal marine resources from the Mammals to the Sponges. The history of a movement of recent years to establish in the West Indies a marine biological station is next fully sketched, and its defence strengthened by a plea based on a comparison of the work achieved by institutions of the desired order existing elsewhere.

The paper shows that, in their utilisation, the marine resources of the West Indian Islands have long played a too limited part in the maintenance of the Colony itself, and that they fall short through being nowhere under the control of an organised plan. The yearly value of the fish caught is estimated at 30,000*l*., against that of fish imported at 147,000*l*., which is thus nearly five times the greater, while attention is directed to a diminution in the supply of the West Indian turtle and a decadence in more especially the "sea egg" industry, due to the effects of over-fishing and lack of scientific treatment, and, in the case of the turtle, due also to the "ceaseless capture of adults." Dr. Duerden, in discussing the remedies for these shortcomings, shows conclusively that they lie in a restocking process to be based on a practical knowledge of the life-history of the species rather than the establishment of closed seasons. Perusal of his paper shows that the importance of these two industries to the traders and inhabitants of the islands is so great that, under the present circumstances, immediate action should be instituted on their behalf.

Concerning the question of fish-capture, Dr. Duerden refers at some length to an unsuccessful attempt made in 1898 to gauge the trawling capacity of certain of the West Indian seas. He gives in full a copy of the log of the vessel employed, and in discussing the alleged failure he expresses the conviction that the venture (which was a private one) was too early suspended, and shows reason to conclude that the further introduction of northern methods without reference to tropical conditions is not likely to be successful. Claiming satisfaction for line-fishing at 200 fathoms, he is led to advocate the stake-net method lately introduced from America as specially fitted for use in bays and lagoons, if not among the coral reefs themselves. His paper shows that he has thoroughly mastered all branches of his subject, and proves beyond previous experience that the West Indian seas contain a rich fauna, which, systematically handled on scientific lines, ought materially to increase the resources of the islands, and thereby to aid in raising them from their present unsatisfactory condition.

Dr. Duerden institutes comparisons between the results obtained at the West Indies and those begotten of trained supervision and the establishment of a fisheries bureau, with its necessary plant and equipment, at the Cape and elsewhere, and he with much naïvety dwells upon the facts as calculated to affect, by competition, the Sponge industry of the Bahamas, financially the most important industry the Colony can boast. He points with justifiable emphasis to the need in the West Indies of a fisheries establishment, regarding it as a pressing necessity to enable the colonists to keep pace with the times and fully to maintain their position in competition and advancement beside the rest of the world.

Conspicuous among the marine biological establishments to which he points as exemplary, are those which have arisen in relation to the agricultural departments of localities at which they are placed; and the suggestion arises that a similar extension should be granted the Agricultural Department of the West Indies, now wholly botanical. Of the success which has attended the work in economic botany which Dr. D. Morris, the indefatigable director of this Department, has achieved in the short period which has elapsed since its foundation, our readers are aware; and we are informed by a local authority that he is eminently desirous of the extension of his sphere of influence in the direction of economic zoology. In Dr. Duerden he has at hand the one man who, by training and experience, is most familiar with the neighbouring West Indian seas and all that pertains to fisheries work upon them. Perusal of Dr. Duerden's paper is convincing as to the urgency of this matter, and we consider that the Government and those in charge of the Agricultural Department of the West Indies would be well advised did they provide, properly equipped, a laboratory of which he should be put in charge. To do so would be but to give the Department equal chances with others under Imperial control, to which it is closely akin.

Concerning the economic zoology of the West Indian seas then, everything tends to show that at the present time circumstances so combine that it may be said all is ripe for the initiation of a new departure, under which systematic work and organisation, guided by the light of science, may be profitably brought to bear. The local Press are advocating this course, and the special publication of Dr. Duerden's paper is the expression on the part of those best competent to judge of its desirability. Given this, and the scientific knowledge of the movements and life-histories of the denizens of the seas which would thus be obtainable, the hatcheries, curing-houses, wharves and trading-fleet would follow in due course; and it is certain that a moderate amount of assistance bestowed in the direction we have indicated might be the means of placing the depressed colonies in an improved position, and of thereby lessening their constantly-recurring charge upon the mother country.

THE LATE MR. SEEBOHM'S TRAVELS IN ARCTIC EUROPE AND ASIA.[1]

THE two well-known volumes, respectively entitled "Siberia in Europe" and "Siberia in Asia," in which Mr. Seebohm described his bird-nesting expeditions to the Petchora (1875) and Yenesei (1877) valleys, having long been out of print, the author determined to combine (and to some extent condense) the two narratives, and to issue them in single volume form. The greater portion of this task had been accomplished when it was unhappily brought to an abrupt close by the untimely death of the talented author. Its completion was thus of necessity left to another hand. Although the editor has not thought fit to make his identity known to the public, he may be congratulated on the tact and skill with which he has carried out his share of the work.

In one respect, and one respect only, are we disposed to find fault with the editor; and this in regard to the title chosen for the volume. In this respect, indeed, both author and editor are singularly unfortunate. "Siberia in Europe," the title of the first volume of the original work, is a geographical absurdity, and "Birds of Siberia" is but little, if at all, better. For, in the first place, at least half of the tract of country through which the author travelled has not the faintest shadow of a claim to be termed "Siberia," and, secondly, birds form by no means the sole topic on which the author discourses. "Egg-hunting in high latitudes," or some such title, would, we think, have been a far preferable designation.

Since Mr. Seebohm's account of his journey along the Yenesei was reviewed at considerable length in these columns when the original work was published, a very brief notice will suffice on the present occasion. The author's main object was to obtain nests, eggs and young of birds whose breeding habits were previously almost or entirely unknown; and his success in discovering the breeding places of the grey plover, little stint and other kinds of his favourite "Charadriidæ" are now matters of history. Migration was also a favourite subject of study and speculation on the part of Mr. Seebohm; and although we may be unable to assent to all his views and opinions with regard to this phenomenon, his account (p. 203) of the rush of migrating birds on Heligoland must remain fresh and interesting for all time.

"From the darkness in the east," he writes, "clouds of birds were continually emerging in an uninterrupted stream; a few swerved from their course, fluttered for a moment as if dazzled by the light, and then gradually vanished with the rest in the western gloom. . . I should be afraid to hazard a guess as to the hundreds of thousands that must have passed in a couple of hours . . . . The scene from the balcony of the lighthouse was equally interesting; in every direction birds were flying like a swarm of bees, and every few seconds one flew against the glass."

And Mr. Seebohm is equally happy when describing the habits of the birds and their young on the tundra, which formed the main object of his expeditions. The most striking illustrations in the book are undoubtedly those of the nest and young of the grey plover and little stint, but as these appeared in NATURE on a former occasion they are not repeated here, and we prefer to

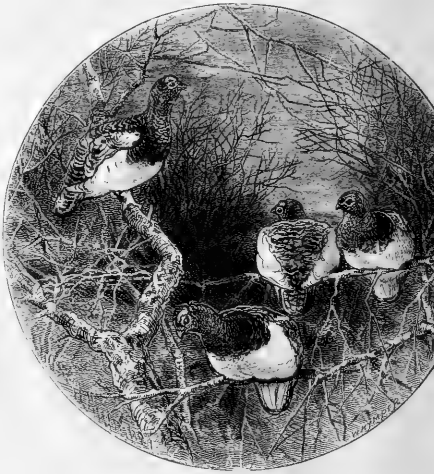

FIG. 1.—A group of willow-grouse. (From "The Birds of Siberia.")

give, as an example of Mr. Whymper's illustrations, the exquisite cut of willow-grouse which stands at the head of chapter xii.

But, as we have already indicated, Mr. Seebohm by no means confined his attention to birds, and his notes on the Samoyedes of the Petchora should form interesting reading to all students of anthropology, while his observations on reindeer can scarcely fail to attract all those who make a special study of the deer tribe. The sportsman, too, will find much interesting matter in many of Mr. Seebohm's pages.

Our opinion of the manner in which the editor has carried out his task has been already expressed; but we think he would have been wiser had he cut out the penultimate paragraph of the last chapter, which contains certain very unnecessary reflections on the mode of zoological work in vogue in this country.

As an interesting and well-written account of two adventurous journeys through little-known mosquito-haunted regions, the work should attract a large circle of readers.

SCOTCH SCENERY AND GEOLOGY.[1]

THE five-and-thirty years which have elapsed since the first edition of this work appeared have witnessed great advances in certain departments of geology, especially those which are all-important in that of Scotland. In 1865 the northern and central Highlands were confidently asserted to be metamorphosed Silurian sediments, and the complexities of the southern uplands were unsuspected. Now the secret of the Highlands and the mystery of the Lowlands have been discovered, thanks mainly to Prof. Lapworth, and although riddles yet remain unsolved in the former, particularly near the southern border, the members of the Survey can work with confidence on their leading principles of interpretation. Even since 1887, the date of the second edition, no small advances have been made, so that we are not surprised to read that the present edition has been thoroughly revised and considerably enlarged. Since the first one, in fact, the greater part of the book has been rewritten, and so much new matter incorporated that we soon lose our way in trying to compare the two volumes page by page. In some respects there are omissions, for several points, open to debate in 1865, may now be taken for granted; while on others, opinions then commonly entertained are now repudiated. For instance, we are no longer told that the greywacke and shale of the southern uplands have been in some places changed into serpentine, felstone or granite.

FIG. 1.—Brig o' Trams Wick. (Cliffs of Old Red Flagstone, illustrating bedding, joints and weathering.)

But, though many disputed points are now settled, others still remain. Personally, we should not assume that an ice-sheet had crossed from Scandinavia to the eastern coast of England, or had deposited the boulder clay on the northern heights of London; we should not have left, without fuller discussion, the possibility of the larger lake basins being mainly formed by earth flexures after the valleys had been excavated; nor should we have so readily accepted the parallel roads of Lochaber as produced on the shores of lakes the waters of which were retained by dams of ice. But time will settle these disputes, as it has settled, during the last quarter of a century, differences yet more fundamental. Enough to say that the new edition of "The Scenery of Scotland" ought to be the companion of every one who does not visit the country merely to kill animals or to say he has been there. The itineraries at the end, with their references to the volume, and the four maps, bringing out so clearly the geology and physical features, will teach the traveller, pleasantly and as easily as may be, to interpret the works of nature in that wonderful land.

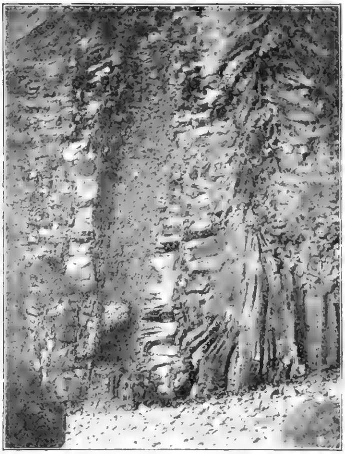

FIG. 2.—Erect Coniferous tree in basalt, Gribun, Isle of Mull.

The excellent illustrations—much more numerous and far better executed than those in the first edition—of which we give specimens, will greatly help the learner. Besides this, the book, though so much enlarged, has not lost its original literary charm. We have always considered the first edition to rise even beyond the high level which the author is wont to maintain, and so took up this with some apprehension that, as often happens in real life, the child had lost its beauty in growing up. A change there has been; the book has reached its full stature but retains its attractiveness, while it has increased in power. Hence, in congratulating Sir Archibald Geikie

[1] "The Scenery of Scotland viewed in Connection with its Physical Geology." By Sir Archibald Geikie. Third edition. With four maps and numerous illustrations. Pp. xxii + 540. (London: Macmillan and Co. Ltd., 1901.) Price 10s. net.

on this appropriate close to his more professional work, we express an earnest hope that it will be not a few years before the inevitable *finis* is written on his scientific and literary career. T. G. B.

DINNER TO SIR ARCHIBALD GEIKIE.

THE complimentary dinner to Sir Archibald Geikie on May 1, provided a means of giving public expression to the regard in which he is held, not only in the scientific world, but also by leaders in other branches of intellectual activity. The representative character of the dinner was very noteworthy, as will be seen from the following list of those present :—

Rt. Hon. Lord Avebury, Sir Archibald Geikie, Sir G. G. Stokes, Bart., Sir F. Abel, Bart, Major-General Sir J. Donnelly, Admiral Sir. W. Wharton, Sir John Evans, Sir Norman Lockyer, Sir Henry Craik, Sir John Murray, Sir Michael Foster, Sir William Turner, Sir Henry Howorth, Sir Henry Roscoe, Sir Lauder Brunton, Major-General Festing, C.B., S. Spring-Rice, C.B., Digby Pigott, C.B., Major-General McMahon, Colonel Johnston, Colonel Bushe, Major Craigie, Rev. Prof. Bonney, Rev. Prof. Wiltshire, Prof. T. McK. Hughes, Prof. Sollas, Prof. Ray Lankester, Prof. C. le Neve Foster, Prof. J. Geikie, Prof. E. Hull, Prof. Joly, Prof. Jack, Prof. Corfield, Prof. Lapworth, Prof. Watts, Prof. Seeley, Prof. Garwood, Prof. T. Groom, Prof. G. A. J. Cole, Prof. W. Galloway, Prof. H. Bauerman, Prof. R. A. Gregory, Prof. Evan Small, Dr. F. Moreno, Dr. W. Blanford, Dr. P. L. Sclater, Dr. Scharff, Dr. F. Parsons, Dr. George Ogilvie, Dr. Tempest Anderson, Dr. Horace Brown, Dr. Scott Keltie, Dr. Hugh R. Mill, Dr. J. W. Evans, Phipson Beale, K.C., H. Arnold Bemrose, J. E. Bartholomew, E. Best, F. Best, C. Borchgrevink, B. H. Brough, G. L. Craik, C. Fox-Strangways, Roderick Geikie, E. Greenly, George Griffith, A. Harker, R. S. Herries, T. V. Holmes, W. H. Hudleston, R. L. Jack, D. A. Louis, J. E. Marr, F. Macmillan, G. A. Macmillan, H. W. Monckton, George Murray, E. T. Newton, Grant Ogilvie, J. Parkinson, F. W. Rudler, A. Strahan, H. J. Seymour, J. J. H. Teall, C. Tookey, W. Whitaker, H. B. Woodward, Martin Woodward.

FIG. 3.—Rock terraces of old sea margins, Isle of Jura.

The list shows that the different public departments with which the Geological Survey is most closely connected were well represented, including the Treasury, Admiralty, Board of Education, Local Government Board, Board of Agriculture, Ordnance Survey, Scottish Education Office, Stationery Office and British Museum. There were likewise present the professors of geology in London, Oxford, Cambridge, Edinburgh, Dublin and Birmingham, together with numerous other Fellows of the various learned societies. Letters, telegrams and addresses of felicitation were received from all parts of Europe and America. The following telegram from Christiania was read by the chairman: "Also from Norway's mountains an echo of the cheers for the master of English geology—Brögger, Helland, Nansen, Reusch, Vogt."

Lord Avebury, in proposing the health of the guest of the evening, said :—

Sir Archibald was educated at the Royal High School and University of Edinburgh, which must indeed be very proud of him. He commenced his official career in 1855, when, at the early age of nineteen, he was appointed to a post on the Geological Survey, and in 1867 was made director for Scotland. In 1871 he became professor of geology at Edinburgh, and held the post till 1881, when he resigned it on his appointment as director-general of the Geological Survey and director of the Museum of Practical Geology in Jermyn Street, which he has since held with credit to himself and great advantage to geological science. Every one would admit (1) that the Geological Museum was a model museum, (2) that the Geological Survey has been admirably managed and that Sir Archibald has organised a splendid staff, (3) that the maps and memoirs of the Geological Survey are admirable contributions to science and an honour to all concerned.

Sir Archibald was one of the first field geologists to realise the value of microscopic sections of rocks, and under his superintendance some thousands of slides were made and added to the Jermyn Street Museum. Under his able successor, whom we all congratulate on his appointment, we may be sure that this branch of the science will not be negelcted.

Besides his official duties Sir Archibald has contributed to the progress of science by much original work, comprising nearly 100 separate memoirs; to scientific education by his primers and text-books, which are models of clearness; to scientific literature by his admirable "Text-book of Geology," his "Geological Sketches at Home and Abroad," "Founders of Geology," "Memoir of Ramsay," "Life of E. Forbes," "Life of Murchison," &c.

Others also of his books are important as contributions to science, and also in rendering it more accessible and more interesting to the general reader, such as his charming "Scenery of Scotland" and "The Ancient Volcanoes of Britain." These seem to me models of what such books should be, combining, as they do, scientific accuracy with a love of scenery, and the power of description in happy and expressive words, for Sir Archibald combines with the striking qualities of a geologist those of an enthusiastic lover of nature. He is an artist in two senses, both with pen and pencil, for his sketches add much to the vividness and clearness of his writings.

Our countrymen have not always received fair play from foreigners, but I am happy to say that, among men of science at any rate, the most friendly and harmonious relations exist; we cordially acknowledge the splendid services they have rendered to science, and recognise that, in this respect at any rate, our international relations are pleasant and harmonious. For this also we are greatly indebted to Sir Archibald Geikie.

Sir Archibald is now retiring from his official duties, and the additional leisure which he will enjoy will in great measure, we may be sure, be devoted to the prosecution of geological research.

He has received many well-deserved honours. He was made F.R.S. before thirty; has been vice-president and foreign secretary of the Royal Society and received a Royal Medal; also the Macdougal-Brisbane Medal of the Royal Society of Edinburgh, and the Wollaston and Murchison Medals of the Geological Society. He is an associate of most of the chief academies of Europe and America, D.C.L. of Oxford, D.Sc. of Cambridge and Dublin, and LL.D. of Edinburgh and St. Andrews. He received the honour of knighthood in 1891.

But it is not merely to do honour to a great geologist that we are here to-night, but to express our warm feelings towards an old and valued friend and to congratulate him on his well-earned honours. Sir Archibald, we drink your health, and for our own sakes, as well as for yours, we hope that you have before you many years of health and happiness.

The chairman then presented Sir Archibald with an illuminated address from his colleagues of the Geological Survey and Museum in the following terms:—"We desire, upon the close of your tenure of office, to express our sense of the high value of the services which you have rendered to these Institutions; we proudly recognise the high position attained by you in the scientific world and gratefully acknowledge the beneficial influence of your example. That you may long live, after more than forty-five years in the public service, to enjoy your freedom from official cares and to enrich geological literature with your luminous writings is our earnest desire."

Sir Archibald Geikie replied as follows:—

You may well believe that on such an occasion as this it is hardly possible for a man adequately to express the feelings that overpower him. If "silence is the perfectest herald of joy," this is no less true of gratitude. Hence, were that permissible, I would fain simply thank you in the fewest words for this manifestation of your friendly regard. To you, my lord, I am deeply indebted for all the kind words you have been pleased to say of me and my work, and to you, my friends, my debt is not less for the way in which these kind words have been received and re-echoed by you. The feeling, next to overpowering gratitude, which rises uppermost in my mind is a bewildering wonder why so much kindly appreciation and good-will should have been in this way showered upon me. And yet on reflection I recognise that it is only the culmination of what has been so liberally extended to me all my life. When I look back into the past, the vista of fifty years seems to me crowded with friendly faces and helpful hands, ready at every turn with wise counsel or stimulating sympathy and encouragement. Most of these voices have long been silent for ever, but their sound still lingers in my ears. It is to their aid and guidance that I stand mainly indebted for anything that I have been able to do in the cause of science, and I should be ungrateful and unworthy if on this memorable occasion I failed to acknowledge my indebtedness.

At the outset of my career there were four men who specially befriended me and set me in the path which I have followed ever since. The first of these was James Pillans, professor of Latin (or Humanity as it is called in the north) in the University of Edinburgh. As he was teaching for more than half a century, a large part of the population had passed through his hands. Robert Chambers used humorously to divide mankind into two sections—those who had been under Pillans and those who had not. I am glad to have belonged to the former section. Pillans's name is perhaps most widely known from the savage and wholly undeserved slander of him inserted by Byron in his "English Bards and Scotch Reviewers." As I knew him he was a genial old man, with much of the gravity and stiffness of an eighteenth century pedagogue, but with a kindly nature, a vein of chivalrous sentiment and an enthusiasm for classical literature to which his best students owed much. He was an educational reformer well in advance of his time. In particular, he used to insist on the study of physical geography as a necessary accessory in all historical inquiry. When the story of the progress of education in this country is fully written, an honoured place will be given to Pillans. Horace was his favourite author, and as I was fond of turning the odes into English verse and illustrating them with parallel passages from other authors, my exercises procured me first his notice and then his friendship, which he continued to the end of his life. Knowing my taste for geology, he asked me to meet Leonard Horner at breakfast, and in this way indirectly led to my introduction to Lyell and to the Geological Society of London.

Another teacher whose influence and help were great was George Wilson, well known to chemists for his able researches on fluorine, and to a much wider public for his delightful literary essays. In his laboratory I studied chemistry. It was he who first opened out to me the prospect of employment in the Geological Survey and eventually introduced me to Andrew Crombie Ramsay.

Hugh Miller, by his writings, and still more by the personal charm of his conversation, as he discoursed over the fossil treasures in his museum, finally confirmed my determination to give my life up to geology, if that were found to be practicable. It was he who first brought my name before Murchison, then newly appointed Director-General of the Geological Survey.

To William Edmond Logan, Director of the Geological Survey of Canada, it is a pleasure to acknowledge my deep indebtedness. From time to time he used to return to this country, and on each of his visits to his brother, who was a lawyer in Edinburgh, I was privileged to spend long hours with him, while he spread his Canadian maps on the floor and gave me graphic pictures of his life and work, with the help of his well-filled sketch-books and note-books. After such interviews, as you may well believe, the determination to become a geologist took deep root.

At that time, however, now half a century ago, the outlook for employment in a geological capacity was neither very wide nor very clear. Robert Chambers, probably most widely known now as the author of the once famous "Vestiges of Creation," but, I venture to think, best deserving to be remembered for his pioneer work in glacial geology, rather sought to dissuade me from the Survey. I remember that one of the reasons he gave was that he hardly thought I possessed strength and appetite enough for the life of a professional geologist. He had lately been in Wales with a Survey party, consisting, if I remember, of Ramsay, Selwyn and Jukes, and being the oldest member of the company was unanimously voted into the chair, where he had the duty assigned to him of carving a leg of Welsh mutton. He described the prodigious capacity of the geologists for food, and the incredibly short time that passed before he had nothing but a bare bone in front of him.

In the early autumn of 1855 I had an interview with Murchison at his hotel in Edinburgh. He looked a little doubtfully at my youthful and slight figure, but was reassured by Ramsay, whom I had shortly before taken on a geological excursion in the neighbourhood. The chief remarked to me that a pair of good legs were of about as much use as a head to a geologist. I joined the staff in the following October. Six years later I accompanied Murchison in a long geological tour through the Highlands, and as the climbing all fell to me, he was quite satisfied as to the capacity of my legs. That expedition secured for me his lasting friendship. He never lost an opportunity of aiding me. Underneath a somewhat stiff military manner he carried a warm heart. Among all my benefactors there is none to whom I owe so much and for whose memory I cherish a warmer regard.

The Geological Survey was then a much smaller establishment than it has since become. Originally placed under the Board of Ordnance, its members wore a military uniform; but on the transference of the organisation to the Civil Service this uniform was discarded, though, as in the case of the "poor workhouse boy," the gilt buttons survived, and with their crossed hammers and crown continued for many years afterwards to be sported on the vests of the Survey men at their annual festivities. Who shall describe the delights of the Survey life in the field, when what had been the employment only of an occasional precious holiday, became the absorbing occupation of one's life? We had pessimists on the staff then as now. One of these continually reminded us that as ours was a service depending for its maintenance upon an annual vote of Parliament, which might some fine day be refused, we should all hold ourselves prepared to find something else to do.

When I joined the staff the system of Civil Service examinations had lately been authorised by Act of Parliament, but had not yet been brought into working order. I used to be warned from time to time by one lugubrious member of the Department that I had better get myself examined in time, otherwise I would probably endanger my pension, if I lived long enough to claim it. But I knew that, as the examinations were then framed, I should infallibly be plucked. I could not, for example, have given the precise ages of each of Henry the Eighth's wives, nor could I have done a sum in compound addition three feet long in ninety seconds. So I thought it best to let a sleeping dog lie. I never passed any examination, and I am happy to assure you that the Treasury has not refused me my pension.

No member of the Survey who served under Ramsay will ever forget the charm of his presence, his radiant good humour, his unvarying helpfulness, his acuteness in criticism, his sagacity in geological discussion and the little petulances and whims that made his society so irresistibly amusing. His beneficent influence was long one of the great features of the service, and we owe to him, not only the recollection of his delightful personality, but the guidance and encouragement which have carried us through our work.

To my colleagues in the Survey who have prepared and signed this beautiful address my heartiest acknowledgments are due. It will remain with me as a precious memorial of many close and enduring friendships. Each signature will remind me, now of some delightful ramble in the country when geological problems were eagerly discussed on the ground, now of some momentous conference in the office when the plan of campaign or the details of maps and memoirs were fully considered and settled.

During my tenure of office as Director-General I have been ever supported by the loyal and unstinted devotion of the staff. It has been an honour and a pleasure to be placed at the head of such a body of men—so enthusiastic in their whole-hearted consecration to science and so unwearied and loyal in their efforts for the interests of the service. I feel sure that in no branch of the public service could the *esprit de corps* be higher than it has been among us. You can well understand that it is impossible without regret to sever one's connection with comrades such as these. At the end of my official career, however, I can truthfully claim to have striven to the utmost of my power for the welfare of the staff and for the scientific renown of the service. I have sought to secure the very best men whom it was possible to obtain, and I feel very confident that the Geological Survey, as regards the zeal, capacity and attainments of its members, may challenge comparison with any scientific institution in any country of the world. I rejoice to think that the service is being now put on a firmer footing than it has ever held before, that the prospects of pay and promotion have been lately broadened and brightened, and that, under the guidance of my distinguished friend and successor, the Survey may look forward to a future even more illustrious and more useful than its past. Gentlemen, I thank you all once more from the very bottom of my heart.

THE ROYAL SOCIETY SELECTED CANDIDATES.

FOLLOWING our usual course, we print the qualifications of the fifteen candidates selected by the Council of the Royal Society on Thursday last, for election into the Society:—

ALFRED WILLIAM ALCOCK,

Major, I.M.S., M.B., C.M.Z.S. Superintendent of the Indian Museum; Professor of Zoology in the Medical College, Calcutta. Distinguished as a zoological investigator and teacher, and as a museum curator. Was Surgeon Naturalist to the Marine Survey of India, from 1888 to 1892, on board the Royal Indian Marine Ship *Investigator*, also to the Pamir Boundary Commission in 1895. Has devoted himself chiefly to the study of marine zoölogy with especial reference to fishes, crustacea, echinoderms and madreporaria, and to problems connected with the geographical distribution of the Indian representatives of these groups, and the phenomena of viviparity in fishes. Author of an extensive series of memoirs, papers and reports dealing with the aforementioned subjects, published during the past ten years in the *Proceedings* of the Royal Society, the *Journal* of the Asiatic Society of Bengal, the *Annals and Magazine of Natural History*, and in the series of publications of the Indian Museum, and "Scientific Memoirs" by the Medical Officers of the Indian Army, and elsewhere. Some of these (*e.g.* the series entitled "Materials for the Carinological Fauna of India") are revisionary monographs of the groups with which they deal, and in others (*e.g.* the Survey of the Deep Sea Zoological work of H.I.M.S. *Investigator* for 1884–1897, and the "Deep Sea Madreporaria") the general bearing of the zoogeographical problems arising out of the work are fully discussed in their association with the facts and theories of oceanographical research. In connection with the work of the *Investigator* he originated, in 1892, the serial publication, "Illustrations of the Zoology of the *Investigator*," now progressing.

FRANK WATSON DYSON,

M.A. (Cantab.), Chief Assistant (since 1894) Royal Observatory, Greenwich. Late Fellow of Trinity College, Cambridge. Secretary of Royal Astronomical Society. Author of various papers on mathematics and astronomy, among which may be mentioned:—"The Potential of Ellipsoids of Variable Densities" (*Quart. Journ.*, Pure and Applied Mathematics, No. 99, 1891); "The Potential of an Anchor Ring" (two papers—*Phil. Trans.*, 1893, pp. 43–95 and 1041–1106); "The Motion of a Satellite about a Spheroidal Planet" (*Quart. Journ.*, Pure and Applied Mathematics, No. 105, 1894); "The Effect of Personality in Observations of the Sun's Right Ascension on the Determination of the Position of the Ecliptic" (with W. G. Thackeray, *Monthly Notices, Roy. Astron. Soc.*, vol. liv., 1894); "Account of the Measurement and Comparison of a set of four Astrographic Plates" (with W. H. M. Christie, *ibid.*, vol. lv., 1894); "On the Determination of the Positions of Stars for the Astrographic Catalogue at the Royal Observatory, Greenwich" (with W. H. M. Christie, *ibid.*, vol. lvi., 1896); "New Division Errors of the Greenwich Transit Circle and their Effect upon the observed N. P. D.'s (with W. G. Thackeray, *Mem. Roy. Astron. Soc.*, vol. liii., 1899); "Comparison of the Diameters of the Images of Stars on the Greenwich Astrographic Plates, with the Magnitudes given in the 'Bonn Durchmusterung'" (with H. P. Hollis, *Monthly Notices, Roy. Astron. Soc.*, vol. lx., 1899). Distinguished as an astronomer.

ARTHUR JOHN EVANS,

M.A. Hon. Fellow of Brasenose College, Vice-President of the Society of Antiquaries, Keeper of the Ashmolean Museum, Oxford. Distinguished as an archæologist and anthropologist. Mr. Evans's recent discoveries in Crete have been of the highest importance as throwing an entirely new light on the early civilisation of the Ægean and Mediterranean areas, and proving the hitherto unknown fact that a Præ-Phœnician form of writing was in use within those areas during the Mycenæan period. Starting from certain engraved gems, some of them found in Crete, the figures on which he suspected to be alphabetic or syllabic signs, he was led by inductive reasoning to infer that in that island there must exist monuments of a præ-historic system of writing. For some years he has carried on investigations in Crete, with the final result of bringing to light, in what seems to be the Palace of King Minos, or the famous Labyrinth, upwards of a thousand clay tablets, inscribed with documents in both a pictographic and a linear system of writing, as well as remains of artistic work of remarkable interest. The existence of a high stage of Mediterranean culture, about 2000 B.C., has thus been established, and the use of writing among Hellenic peoples has itself been carried back to a date at least 500 years earlier than has hitherto been regarded as possible. Of Mr. Evans's other published works may be cited his researches in the anthropology and antiquities of Illyricum and Dalmatia, and his numerous memoirs relating to the Iron Age, the Mycenæan Period, the late Celtic or Early Iron Period, and generally the connection of Egypt and the East with the dawn of European civilisation. His works on the coinages of Tarentum and Sicily are standard authorities, and after the death of Prof. Freeman he completed that eminent writer's "History of Sicily."

JOHN WALTER GREGORY,

D.Sc., F.G.S. Professor of Geology in the University o. Melbourne. Explorer of Mount Kenya, and author of "The Great Rift Valley." Has contributed a large number of papers to] scientific publications on Palæontological, Petrological and Physiographical questions; for example, on the Maltese fossil Echinoidea (*Trans. Roy. Soc.*, Edin.); on British Palæogene Bryozoa (*Trans. Zool. Soc.*); on the Echinoidea of Cutch and on the Corals of Cutch (Palæont. Indica); on Pseudodiadema Jessoni; on Archæodiadema; on Echinocystis, &c., besides the volumes in the British Museum Catalogue on the Jurassic and the Cretaceous Bryozoa. In Petrology he has written in the *Quarterly Journ. Geol. Soc.* on the Tudor specimen of Eozoon, the Variolites of the Fichtelgebirge, the Waldensian Gneisses, the Schistes Lustrées of Mont Jovet, the Geology of British East Africa (three parts), and (in collaboration) the Variolites of the Mont Genevre, the Geology of Monte Chaberton, the Eozoonal structure of ejected blocks, Monte Somma, &c., and among several papers in Physical Geology, the Glacial Geology of Mount Kenya, and (in collaboration) Contributions to the Glacial Geology of Spitzbergen.

HENRY BRADWARDINE JACKSON,

Captain, R.N., Naval Attaché to the British Embassy, Paris. Invented (1886) a practical system of electrically illuminating gun sights for firing at night, which was adopted and used for some years in H.M. Navy, but has since been replaced by later methods. Proved (1888) that considerable stability is necessary in order that a totally submerged automobile torpedo may maintain a straight course. Has given much attention to the theory and practice of aërial telegraphy. Invented a serviceable apparatus for signalling between ships at sea without wires. Proved that if the Hertzian oscillations are transmitted and received by vertical wires, the distance to which effective signals can be sent tends to vary within limits as the product of the lengths of the wires.

HECTOR MUNRO MACDONALD,

M.A., Fellow of Clare College, Cambridge. University Lecturer in Mathematics. Distinguished for original work in Mathematics and Mathematical Physics. Author of the following papers:—"Torsional Strength of a Hollow Shaft" (*Proc. Camb. Phil. Soc.*, viii.); "Self-induction of two Parallel Conductors" (*Trans. Camb. Phil. Soc.*, xv.); "Waves in Canals" (*Proc. Lond. Math. Soc.*, xxv.); "Waves in Canals and on a Sloping Bank" (*ibid.*, xxvii.); "Electrical Distribution on a Conductor bounded by two Spherical Surfaces cutting at any Angle" (*ibid.*, xxvi.), and a Note on the same (*ibid.*, xxviii.); "Electrical Distribution induced on a Circular Disc placed in any Field of Force" (*ibid.*, xxvi.); "Electrical Distribution induced on an Infinite Plane Disc with a Circular Hole in it" (*ibid.*, xxvii.); "Electrical Distributions on Cones" (*Camb. Phil. Soc. Trans.*, "Stokes memorial" volume); "Note on Bessel Functions" (*Proc. Lond. Math. Soc.*, xxix.); two papers on the Zeroes of the Bessel Functions (*ibid.*, xxix. and xxx.); "Zeroes of the Harmonic $P_n^m(\mu)$ considered as a Function of μ" (*ibid.*, xxxi.).

JAMES MANSERGH,

M.Inst.C.E., Civil Engineer. President of the Institution of Civil Engineers. Author of "Lectures on Water Supply, Prospecting for Water, Prospecting and Boring," delivered at the School of Military Engineering, Chatham, also of "The Supply of Water to Towns," and other works. The designer of the waterworks and sewerage of Lancaster, Lincoln, Stockton, Middlesbrough, Rotherham, Southport, Burton-on-Trent, Melbourne (Australia), Birmingham and many other towns. These designs include some of the largest schemes of water supply and drainage ever carried out. Author of about 140 reports upon schemes of water supply, sewerage or sewage disposal for Halifax, Hereford, St. Helens, Darlington, Whitby, the Potteries, Derby, Southampton, Durham, Shrewsbury, Malvern, Cambridge, Edinburgh, Plymouth, York, Antigua, Philadelphia (U.S.), and other places. Was a member of the Royal Commission on Metropolitan Water Supply. Eminent as a hydraulic engineer.

CHARLES JAMES MARTIN,

M.B., D.Sc. (Lond.). Professor of Physiology in the University of Melbourne. Is eminently distinguished as an original investigator in Physiology. His chief original papers deal with the Chemistry and Physiological Action of Snake Venom, and with the action and reaction of Toxins and Antitoxins. Author of:—"The Chemistry of the Venom of the Australian Black Snake" (*Proc. Roy. Soc.*, N.S.W., 1892); "The Physiological Action of the Venom of the Australian Black Snake" (*ibid.*, 1895); "Curative Action of Calmette's Serum against Australian Snakes" (*Internat. Med. Journ.*, 1897–98, and *Proc. Roy. Soc.*, 1898); "Nature of the Antagonism between Toxins and Antitoxins" (*ibid.*, 1898, joint Author); "Separation of Colloids and Crystalloids by Filtration" (*Journ. of Physiology*, 1896); "Observations on the Anatomy of the Muzzle of *Ornithorhynchus*," with Dr. Wilson (Linn. Soc., N.S.W., 1892); "Observations on the Femoral Gland of *Ornithorhynchus*," with Dr. Tidswell (Linn. Soc., N.S.W., 1894); "An Investigation into the Effects of the Darling Pea, *Swainsonia galegifolia*" (Agricultural Department of N.S.W.); "Cerebral Localisation in Platypus" (*Journ. Physiol.*, 1899).

RONALD ROSS

Major (I.M.S., retired), M.R.C.S. (Eng.). D.P.H. (United Colleges, London). Pathological Investigator. Distinguished for work on Malaria and Kala-azar (Assam). Commenced these special studies in Tropical Hygiene and Parasitology in 1891. Papers on these subjects and on Histology of Blood, Indian Medical Societies and Journals. Parkes Memorial Prize and Gold Medal (Netley) for Essay on Malaria, 1894. Same year commenced experimental examination of Manson's Mosquito-Malaria theory, and studied malaria parasites at Secunderabad. Determined evolution of "crescents" in stomach cavity of gnats (Manson, *Brit. Med. Journ.*, March, 1896). Established animate nature of the flagellate bodies (*ibid.*, Jan., 1897). Finally succeeded in cultivating malaria parasites in gnats (*ibid.*, December 18, 1897; Feb., 1898). Next year elucidated life-history of a malarial parasite (*Proteosoma Grassii*) of birds; infected numerous healthy birds by bites of gnats, thus establishing mosquito theory. Also investigated Kala-azar (Reports to Govt. of India, 1898–99). Appointed Lecturer in Tropical Medicine, Liverpool School of Tropical Medicine, 1899. Continued malaria investigations in Sierra Leone (Report of Liverpool Expeditions, 1900). Author also of Notes on *Amoeba coli* and *Cercomonas intestinalis* (*Indian Med. Gazette*, 1897); Report on Sanitation of Bangalore, 1896. Also contributor to Quain's Dictionary of Medicine), and wrote "Instructions for Prevention of Malaria," 1900 (used by Government).

WILLIAM SCHLICH,

Ph.D., C.I.E., Doctor of Philosophy of the University of Giessen; Companion of the Order of the Indian Empire: Principal Professor of Forestry in the Royal Indian Engineering College, Coopers Hill. Dr. Schlich is well known for the impetus which he has recently given to the study of Forestry in England. Between 1871 and 1880 he was Conservator of Forests in Sind, Bengal and the Punjab successively, and in 1881 he was appointed Inspector-General of Forests to the Government of India. From 1885 to 1889 he was employed specially in England in organising the first English Forest School; and in 1889 he was appointed to his present office. He is a man in thorough sympathy with Science, and has attained great eminence in that branch of it to which he has devoted most of his life-work. Besides his well-known and comprehensive "Manual of Forestry," he is the author of the following papers:—Various Articles on Scientific Forestry, in the *Allgemeine Forst und Jagd Zeitung*, 1864–67; "The Pyinkado Forests of Aracan," 1869; a Series of Reports on the Forests of Bengal and Assam, 1872–75 [in 1875 he was honorary editor of *The Indian Forester*, which is the leading monthly journal of Forestry]; "The Forests of Darjeeling, Central Provinces, Hyderabad Assigned Districts, Chota Nagpore," 1882–85; "Afforestation in Great Britain and Ireland, Yield Tables for the Scotch Pine, the Douglas Fir, Effects of Forests on Climate, Forestry in the Colonies and India" (*Trans. of Colonial Institute*, 1886–89); "Forestry Education" (*Trans. Royal Arboricultural Soc., Scotland*, 1897); "Timber Supply of the British Empire" (*Imperial Institute Gazette*, 1897).

ARTHUR SMITHELLS,

B.Sc. (Lond.), F.C.S. Professor of Chemistry in the Yorkshire College, Leeds. Distinguished for his Investigations on the Chemistry of Flames. Author of the following Papers (among others): "Some Fluorine Compounds of Uranium" (*Journ. Chem. Soc.*, 1883); "Structure and Chemistry of Flames" (*ibid.*, 1892); "Structure of Luminous Hydrocarbon Flames" (*ibid.*, 1892); "Flame" (Discourse to Brit. Assoc., 1893); "Luminosity of Flames" (*Phil. Mag.*, 1894); "The Structure and Chemistry of the Cyanogen Flame" (*Journ. Chem. Soc.*, 1894, with Dr. Dent); "The Luminosity of Gases,"; "Spectra of Copper and Gold Salts" (*Phil. Mag.*, 1895); "Flame Temperatures and the Acetylene Theory of Luminous Hydrocarbon Flames" (*Journ. Chem. Soc.*, 1895); "The Source of Light in Flames" (*Proc. Roy. Inst.*). Has also taken an active part in improving science teaching in schools. Has edited revised edition of Schorlemmer's "Rise and Development of Organic Chemistry," 1894.

M. R. OLDFIELD THOMAS,

F.Z.S., F.R.G.S., M. Anthrop. Inst. Senior Assistant, Zoological Department, British Museum. In charge of the collection of Mammals in the British Museum since 1878, during which period it has increased materially in extent and completeness. Distinguished for his acquaintance with the structure, history and distribution of Mammals. Author of the

"Catalogue of Marsupialia and Monotremata" in the British Museum, 1888. Joint author with Dr. Sclater of "The Book of Antelopes." Author of upwards of 200 memoirs and papers in various journals on Mammals, their structure and distribution, amongst which are:—"On the Dentition of *Ornithorhynchus*" (*Proc. Roy. Soc.*, 1889); "A Milk Dentition in *Orycteropus*" (*ibid.*); "On the Species of *Hyracoidea*" (*Proc. Zool. Soc.*, 1892); "On Cœnoles, a still existing survivor of the *Epanorthidae* (*ibid.*).

WILLIAM WATSON,

B.Sc., Associate, Royal College of Science, London, and Assistant Professor of Physics. Late University Scholar in Experimental Physics, London University. In conjunction with Mr. Boys and Mr. Bristoe he published a paper on "The Measurement of Electro-Magnetic Radiation" (*Phil. Mag.*, 31–44, 1891). In conjunction with the late Mr. J. W. Rodger he published a paper "On the Magnetic Rotation of the Plane of Polarisation of Light in Liquids" (*Phil. Trans. Roy. Soc.*, 1895). This paper represented the results of four years' work. As Secretary of a Committee of the Brit. Assoc. he has, in conjunction with Prof. Rücker, been conducting a series of comparisons between the Magnetic Instruments in use in the British Observatories, and the results have been published in the Report of the Brit. Assoc. He is still at work on an instrument for comparing Thermometers (see his paper, *Phil. Mag.*, 44–116, 1897). He is now engaged in investigating the connection between the magnetic units employed in Observatories and the Ampere and Ohm.

WILLIAM CECIL DAMPIER WHETHAM,

M.A. Lecturer in Physics. Fellow of Trinity College, Cambridge. Author of the following scientific papers, &c.:—"On the Alleged Slipping at the Boundary of a Liquid in Motion" (*Proc. Roy. Soc.*, xlviii., p. 225, 1890, and *Phil. Trans.*, 1890, A., p. 559); "Note on Kohlrausch's Theory of Ionic Velocity" (*Phil. Mag.*, July 1891); "Ionic Velocities" (*Proc. Roy. Soc.*, lii., p. 283, 1893, translated *Zeits. für Physikal Chem.* xi., p. 220, 1893, also *Phil. Trans.*, 1893, A., p. 337); "On the Velocity of the Hydrogen Ion through Solutions of Acetates" (*Brit. Assoc. Reports*, 1894, p. 568): "On the Velocities of the Ions and the Relative Ionisation Powers of Solvents" (*Phil. Mag.*, 1894); "The Velocities of the Ions" (*Proc. Roy. Soc.*, lvii., p. 182, 1895, and *Phil. Trans.*, A., 1895, p. 507); "The Ionising Power of Solvents" (*Phil. Mag.*, July, 1897); "Report to the British Association on the Present State of our Knowledge in Electrolysis and Electro-Chemistry"; "The Theory of the Migration of the Ions and of Specific Ionic Velocities" (*Brit. Assoc. Report*, 1897, p. 227); "The Coagulative Power of Electrolytes" (*Phil. Mag.*, November, 1899); "The Ionisation of Dilute Solutions at the Freezing Point" (a paper read before the Royal Society); an elementary text-book on "Solution and Electrolysis" (Camb. Univ. Press, 1895); Letters and Articles in NATURE and *Science Progress*.

ARTHUR SMITH WOODWARD,

F.G.S., F.L.S., F.Z.S., F.R.G.S., &c. Assistant-Keeper of Geology, British Museum, Natural History, Cromwell Road, S.W. Studied at the Owens College, Manchester, 1880–82; entered British Museum, August 24, 1882; awarded Wollaston Fund by Geological Society, 1889; and the Lyell Medal in 1896. Distinguished for his knowledge of Fossil Fishes. Author of 150 separate papers, mostly on Vertebrate Palæontology: (142 on Fossil Fishes; 14 on Reptilia; 4 on Mammalia; and 14 on General Palæontology). Author of two monographs (1890–95) on the Fossils of the Hawkesbury Series (*Mem. Geol. Survey*, New South Wales (Palæontology), Nos. 4 and 9, Museum, Sydney, New South Wales); and on Fossil Crocodilia from the Cretaceous Rocks of Neuquen, Argentine Republic (*Anales Mus. La Plata*, 1896). Author of a British Museum Catalogue of Fossil Fishes, comprising: Part I. "The Elasmobranchii" (pp. i.-xlvii. and 1-474, plates i.-xvii. and 13 woodcuts, 8vo, 1889); Part II. "The Elasmobranchii" *continued* (pp. i.-xliv. and 1-567, plates i.-xvi. and 58 woodcuts, 8vo, 1891); Part III. "The Actinopterygian Teleostomi" (pp. i.-xliii. and 1-544, plates i.-xviii. and 45 woodcuts. (Printed by order of the Trustees, 1895.) Part IV. now preparing for press. Also "Outlines of Vertebrate Palæontology" (Camb. Univ. Press), 1898, pp. i.-xxiv. and 1-470, with 228 illustrations in the text.

REV. JAMES CHALMERS ("TAMATE").

FEW missionaries have been so widely known and so deservedly appreciated as the Rev. James Chalmers, of the London Missionary Society, whose death has recently been reported. Mr. Chalmers was transferred from Raratonga in the Hervey Group to New Guinea twenty-three years ago, and it is in connection with his later field that he has earned a recognition in scientific journals.

Tamate, as Mr. Chalmers loved to be called by his white as well as by his black friends, was a man of tremendous energy and enthusiasm, and he possessed a rare sympathy with the natives that was due to a deep knowledge of their nature and a personal love for them. His name was a password along very nearly the whole of the southern coast of British New Guinea, and in many places for some distance into the interior. Those natives who had only heard of him longed to see him, those who knew him loved him. Till Sir William Macgregor's arrival he had travelled more in British New Guinea than any other man, and, without appliances, he had increased our geographical knowledge of the possession.

It was always a regret to his scientific friends that Tamate did not publish more about the natives concerning whom he knew so much; but he confessed that he greatly disliked the effort of writing down his experiences, though when he did so he could write in a very vivid manner. His first book, "Work and Adventure in New Guinea" (1885), was written in collaboration with the Rev. Dr. W. Wyatt Gill, to whom anthropologists owe so much. In 1887 Chalmers published his very interesting "Pioneering in New Guinea." In the same year he published a paper "On the Manners and Customs of some of the Tribes of New Guinea" in the *Proc.* Phil. Soc. Glasgow, xviii. p. 56. A valuable "Report on the Toaripi and Korari Tribes" was printed in the *Report Austral. Assoc. Advanc. Sci.* ii. 1890, p. 311. In vol. xxvii. (1897) of the *Journal* of the Anthrop. Inst. he published "Vocabularies of the Bugilai and Tagota Dialects, British New Guinea" (p. 139), "Toaripi" (p. 326), "Anthropometrical Observations on some Natives of the Papuan Gulf" (p. 335). Mr. Chalmers has frequently sent ethnographical specimens to various museums. The bulk of one large consignment was acquired by the British Museum. These objects were carefully labelled and were accompanied by a descriptive catalogue, and many of his labels have been copied by Edge-Partington and Heape in their "Ethnographical Album of the Pacific Islands." These collections contained many specimens and the descriptions much information that was not previously known; for example, the collection included the first bull-roarer obtained on the mainland of British New Guinea.

Mr. Chalmers greatly assisted the Cambridge expedition to Torres Straits by lending his mission boat on more than one occasion, and he hospitably entertained several members of the expedition and otherwise rendered valuable aid.

A noble life of self-sacrifice was laid down for the cause of peace, for, according to the telegram, he met a glorious death while endeavouring to stop a tribal fight on the Aird River, a region which had not yet come under missionary influence and over which the Government had no control. A very promising young coadjutor, the Rev. Oliver Fellows Tomkins, who was dearly loved by Chalmers, and twelve students, are reported to have been murdered at the same time.

Since the above was written a telegram has been received confirming the former rumours. Mr. Chalmers, like several other missionaries in New Guinea, has falsely been reported to have been murdered on more than one occasion; but we fear this time the news is only too true.

A. C. HADDON.

NOTES.

SIR W. ROBERTS-AUSTEN, K.C.B., on leaving the chair as president of the Iron and Steel Institute, at the meeting on Wednesday, announced that Mr. Andrew Carnegie had increased the gift of 6500*l.*, which he made last year to the research fund of the Institute, to 13,000*l.*

AT the recent meeting of the U.S. National Academy of Sciences, Mr. Alexander Agassiz was elected president of the Academy. The Henry Draper Medal was awarded to Sir William Huggins for his work in astro-physics. The following were elected foreign associates:—Dr. J. Janssen, M. Lœwy, director of the Paris Observatory, M. E. Bornet, Prof. Hugo Kronecker, Prof. A. Cornu, Prof. F. Kohlrausch, Sir Archibald Geikie and Prof. J. H. van 't Hoff.

THE movement in Cambridge to secure a portrait of Prof. G. D. Liveing has already received large and influential support. The secretaries think that there are many friends of the professor both in Great Britain and abroad who would like to join in the proposal and who have not yet had notice of it. Such friends should apply to Prof. Lewis, Cambridge, who will be glad to receive their names.

MR. W. LANGDON has been nominated for election as the new president of the Institution of Electrical Engineers. M. Mascart has been elected an honorary member of the Institution.

PROF. ZEILLER, professor of palæobotany at the Paris School of Mines, has been elected a member of the section of botany of the Paris Academy of Sciences, in succession to the late M. Chatin.

A MEETING of the Institution of Mining Engineers will be held in the rooms of the Geological Society, Burlington House, on May 23-25, with Mr. H. C. Peake as chairman. Among the subjects of papers to be read or taken as read are the field-work of photographic surveying as applied in Canada; gold-dredging; the production of copper and its sources of supply; geology of the mineral deposits of the Transvaal; and auxiliary ventilation.

AN expedition against the Anopheles mosquito will be despatched this month to West Africa, under Major Ronald Ross, by the Liverpool School of Tropical Medicine. A leading Glasgow citizen has placed at the disposal of the school and Major Ross a sum of money sufficient to defray the expenses of one year's trial in some malarious city.

A SPECIAL committee has been appointed by the Trinity House, with the deputy-master, Captain G. R. Vyvyan, as chairman, to carry out numerous practical experiments with sound-producing instruments as coast fog signals at St. Catherine's Point, in the Isle of Wight, including comparisons between different forms of sirens and reed instruments sounded by means of compressed air, the observations being made from the Trinity steamer *Irene* at various distances and under varying conditions of weather, &c. The committee will have the advantage of Lord Rayleigh's advice and assistance in the investigations. Representatives of the Admiralty, the Board of Trade, and of the Northern and Irish Lighthouse Boards will also be present.

REFERENCE has frequently been made in these columns to the enlightened and progressive way in which agriculture is carried on in New South Wales and other Australian colonies. Every advantage is taken of modern methods, and the bearings of scientific investigations upon agricultural practice seem to be well appreciated. We are, therefore, not surprised to see in the *Natal Mercury* that Mr. F. R. Moor, Secretary for Native Affairs, who has been on a visit to Australia, has returned to Natal with strong convictions as to the urgent necessity for radical improvements in the methods of agricultural industry in that colony. It is acknowledged that in the past the colony has been depending more upon commercial business as a distributing medium for the interior States than on its productive resources; but the changing conditions demand that the productive capacity should be increased if Natal is to prosper. The obsolete methods of farming now adopted must give place to a system based upon science and carried on with appliances which modern inventive genius has placed at the disposal of agriculture. As Mr. Moor is a member of the Ministry, as well as a farmer of more than average ability, his visit to Australia should not only direct attention to the need for progress in the science and art of agriculture, but also lead to changes which will in the course of time bring Natal into line with other progressive colonies.

THE Board of Trade has given its decision in the inquiry held with reference to the regulation allowing the consumer to veto any change in the pressure at which he is supplied with electric energy. A summary of the evidence given at the inquiry has already appeared in NATURE (vol. lxiii. p. 587). As was generally anticipated the decision now given is in favour of the undertakers depriving the consumer of the absolute power of veto which he has hitherto possessed. In future, when the consumer shall refuse to consent to the change after the undertakers have offered to comply with the conditions laid down by the local authority and to pay the reasonable costs of making the change, the undertakers can appeal to the Board of Trade. The Board may give their consent to the change under such conditions as they may think fit, and this consent shall reckon as equivalent to the consent of the consumer. The Board may, if they consider it desirable, refer to a single arbitrator the question as to what terms and conditions it would be proper to impose, the arbitrator being appointed by themselves.

THE recent conversazione held by the American Institute of Electrical Engineers at Columbia University appears to have been a great success. According to an American contemporary, one of the most interesting exhibits was that made by Mr. P. C. Hewitt, who showed a number of electric vacuum-tube lamps. The lamps consist of glass tubes filled with mercury vapour, through which a current of electricity is passed. The positive electrode is of iron and the negative of mercury. The lamps are arranged to burn directly on the ordinary 100- or 200-volt lighting mains, but they need an extra high voltage to start them, this being obtained by the use of a Wehnelt interrupter or by other suitable means. The light is said to be very steady and brilliant, but poor in red rays; the disagreeable colour due to this defect can, it is stated, be avoided by the use of red reflecting screens. Lamps of 500 and 1000 candle-power were shown burning on the 115-volt direct current mains, the consumption of energy being only half a watt or less per candle. This is much in advance of any other artificial light, and if the lamps can be made commercially in a convenient form and for small candle-powers they should have a great future before them.

WE have received from Dr. J. M. Pernter, director of the Austrian Meteorological Service, an interesting account of the present state of modern "weather-shooting" as practised in Austro-Hungary and Italy—being a reprint of an article contributed to the journal *Die Kultur* (Vienna). The modern experiments were inaugurated by M. Stiger, Burgomaster of Windisch-Feistritz in Steirmark, and the apparatus, consisting of a mortar with a long funnel, was improved by M. Suschnig, of Graz. The theory is that by firing large charges of gunpowder a series of atmospheric rings or whirls are generated and that they penetrate the clouds with sufficient force to prevent the formation of hail, or to disperse it. The idea gained ground so rapidly that, at the present time, there are no less than some 1400 shooting stations in Hungary and many more similar stations in Italy. Dr. Pernter and others were delegated by the Austrian Ministry of Agriculture to witness and report upon the results of experiments as to the efficacy of the system. The experiments were made both in horizontal and vertical directions, with the result that in the horizontal direction the whirls which on leaving the mortar attained a velocity of, say, 170 miles an hour were reduced, at a distance of 80 to 100 metres, to less than 100 miles an hour, and in the vertical direction an initial velocity of 200 miles an hour was reduced to about 75 miles an hour at a height of about 110 metres. It was estimated by Dr. Pernter that the whirls would in no case reach a greater height than 400 metres. The only thing that can at present be positively asserted is that it is not impossible that the shooting may sometimes prevent hail; it is, however, improbable that the energy of the whirls—except under the most favourable conditions—can directly influence its formation.

THE unexpected death of Dr. Kohlstock, which occurred at Tientsin on April 15, causes a great loss to the medical department of the German Army, in which he was regarded as one of the best and ablest organisers. At the time of his death he was forty years of age and was sent, some months ago, to Tientsin, with a view to directing the military hospital there. Prof. Kohlstock will be best remembered in this country by the conspicuous part he played in 1896 in his capacity as Prof. Robert Koch's first assistant during the former's sojourn in South Africa for the purpose of investigating and combating the rinderpest. In Germany, however, his name is associated with several other by no means less important scientific researches. In 1890 he began some special bacteriological studies under the superintendence of Prof. R. Koch, and in the following year the "Seminar für orientalische Sprachen" was founded in Berlin, and Dr. Kohlstock, upon Prof. Koch's recommendation, became lecturer on tropical hygiene at that institute. To his connection, as a teacher, with this institute he mainly owes the title of professor, which was conferred upon him by the German Government in 1898. But his activity and interest were not confined to this work alone, indeed his subsequent appointment as a scientific adviser to the German Foreign Office in matters bearing upon tropical hygiene very largely increased his usual work and brought him into public prominence, with the result that he was soon requested by several private colonial associations to accept a post similar in character to that he held in connection with the Foreign Office, but he declined these offers. His scientific and literary contributions are numerous, but they are entirely devoted to the domain of clinical and bacteriological research in connection with malaria and yellow fever. One popular book, however, which he wrote about two or three years ago is likely to survive him for some time to come, namely, his "Aerztlicher Rathgeber für Ost-Afrika und andere tropische Malaria-Gegenden." Lastly, in conjunction with Prof. Koch he originated the scheme for the establishment of the so-called "Deutsche Anstalt für Tropen-Hygiene," which was recently erected in Hamburg.

MR. J. H. HART'S Annual Report on the Royal Botanic Gardens of Trinidad for the year 1900 deals, as usual, with the botanical and meteorological work in the Gardens, and also the monthly rainfall statistics at some scores of points of observation throughout the island. Several seismographic records were supplied to Prof. Milne, the most important being that of the Caracas earthquake of October 29, the shock commencing suddenly, without any preliminary tremors, and agitating the instrument for two hours. In the herbarium several fungi and parasitic insects injurious to vegetation were under investigation, and also a disease occurring in the cacao plantations of Surinam. A course of agricultural education for elementary school teachers having been inaugurated appears to have proved highly successful, four courses being attended by 112 teachers and 10 cadets. Sugar cane experiments were confined to the raising and trial of new seedlings, and the cultivation of small areas of a few standard kinds for control purposes, no manurial experiments being attempted. From May 1899 to May 1900 there were 170 new canes analysed, 131 being Trinidad seedlings, the rest Demerara, Barbados and standard kinds. The question of the pollination of the cane by wind or insects is still unsettled, but it is found that the greatest variety and the best kinds of canes come from seed harvested where several distinct varieties are planted closely together. Notes are given on the experimental cultivation in the Gardens of rubber, nutmegs, coffee, oranges, guava and other plants. Botanical officials in other West Indian islands supplied as many as seventy varieties of sweet potatoes, but in all cases their yield was very poor.

IN his natural history notes Mr. Hart states that in the St. Ann's and Maraval rivers two species of small fish are found, one not so large as the English stickleback, the other slightly larger. They are commonly found in garden fountains and tanks, and both destroy the larvæ and eggs of mosquitoes. The question of the benefit of introducing these or similar fish into noted malarial districts is well worthy of consideration. It is a fact that the common gold-fish or carp does not increase in their presence owing to the smaller fish devouring the eggs of the larger. Gold-fish, however, are said to destroy mosquito eggs and larvæ. The study of living specimens of insects is rendered difficult by the behaviour of small ants, which attack and destroy nearly every form of insect. All experiments have, therefore, to be conducted in receptacles standing above water. In tapping Para rubber trees it is found that some of the coagulated rubber is cut up and carried away by a large species of black ant. Species of bees, genus Trigona, have also been observed carrying off the coagulated rubber fluid from the stems of *Castilloa elastica*. Similar species use resinous exudations from the *Garcinias* and other trees as ready-made wax for their nests, and in some cases actually cut the bark in such a manner as to cause a flow of the desired fluids.

THE April number of the *Journal of the Franklin Institute* contains the first part of a paper by Mr. Edwin Swift Balch, entitled "Antarctica: a History of Antarctic Discovery." In the introduction to his paper, the author says—"Not long since Sir Clements Markham proposed in the *Geographical Journal*, for November, 1899, to divide the Antarctic into four quadrants, each covering 90° of longitude, and to bear English names. The advantages of this proposition on the score of convenience are not self-evident. Moreover, it is only just to remember that, besides Englishmen, mariners of many other nations have made discoveries in the Antarctic. A letter that I wrote on this matter was published in the *Nation*, New York, May 10, 1900, and also in the *Evening Post*, New York, of the same date. Up to that time I had made no special study of Antarctic geography, and discovered then how difficult it was to find accurate data." In the present instalment the author covers, with considerable detail, (*a*) Voyages leading from a belief to a disbelief in a Terra Australis Incognita, and (*b*) Voyages up to the discovery of a South Polar Continent.

SIR MARTIN CONWAY has drawn up, in the form of a pamphlet entitled "The Rise and Fall of Smeerenburg, Spitsbergen," and privately printed, the results of much careful and laborious investigation into the history of the rival fisheries carried on in Spitsbergen during the seventeenth century. In 1614 the Noordsche or Greenland Company, which had obtained the monopoly of the whale fishery for the Dutch Republic, sent up a force "which the English, under Captain Joseph, were too weak to drive away." They sent some ships to Fairhaven, and probably settled on Amsterdam Island on the flat ground at its south-east angle, the site of the future Smeerenburg, or Blubbertown. Sir Martin Conway traces, so far as they can be traced, the fortunes of Smeerenburg, from its rise in the manner described, to its fall, or rather through its decline, when the whales began to find Fairhaven too dangerous for them. They "began to be shy of the Cookeries and anchorages of the ships, shallops, and what pertained to them; next of the bays, and then of the shallows along the coast, where they were constantly pursued," apparently about 1639; in 1646 "the season was only opened off Smeerenburg, and the whales were then followed to sea or along the north coast." By 1650 the whales had abandoned the banks and Smeerenburg became valueless as a place for trying-out the train-oil. As late as 1671 it remained a place of refuge for refitting ships, but twenty years later nothing was left but the foundations of a few houses. Sir Martin Conway gives many useful references to cartographical and other authorities, and adds a section on the topography and nomenclature of Fairhaven and its neighbourhood.

THE Geological Survey of India has attached to its staff as "Mining Specialist" Dr. F. H. Hatch, who has lately reported on the Kolar gold-field in Mysore (*Memoirs*, vol. xxxiii. part 1, 1901). The auriferous lodes consist of a series of parallel quartz veins in the Dharwar schists, and they conform generally to the direction of the foliation planes of these rocks. They are therefore regarded as "bedded veins," formed by the deposition of quartz and other minerals from solution along open channels or planes of weakness which in general coincided with the foliation of the schists. To this fact is ascribed their lenticular character; they swell and pinch at irregular intervals. As a rule, gold is not visible in the hand-specimens of quartz, which is of a dark bluish-grey colour. In places the quartz has been subject to great stress consequent on the bending of the vein into acute folds, and there it has a well-developed banded or laminated structure. Along the axes of the folds, where the vein is doubled back on itself, large and valuable bodies of ore are found; and where slickensides have been formed by differential movements in the vein, the gold sometimes occurs as a fine film on the smoothed and polished surface. Dr. Hatch deals exhaustively with the methods of working and production of this gold-field.

THE two leading formulæ at present in use in performing interpolations by central differences are due to Newton. In a note reprinted from the *Journal* of the Institute of Actuaries, xxxv. p. 452, Prof. Everett proposes a new formula containing only even differences, which appears to be very simple and convenient.

M. PELLAT contributes to the *Journal de Physique* (April) a short note on the laws of nature in which he points out, as a consequence of the principle of degradation of energy, that, as applied to the universe, the notion of infinite time necessitates that of infinite space.

MR. J. A. THIRD contributes to *Mathesis*, 1900, a short note on trihomologous triangles. Such triangles have three centres of homology, in each of which the lines joining the vertices of one triangle to those of the other are concurrent, the three centres being got by joining different vertices taken in order. They therefore have three axes of homology, on each of which lie the three points of intersection of three sides of the one with three sides of the other. The theorems now proved relate to certain conics connected with the two triangles and lead to a number of particular cases including certain properties of Steiner's ellipse.

TO the May issue of the *Entomologists' Monthly Magazine* Sir George Hampson contributes a long list of abnormalities among Lepidoptera, as illustrated by a series of specimens recently presented to the British Museum by Mr. South, who had spent many years in collecting them.

DR. C. S. MINOT sends us a copy of "Notes on Anopheles," which recently appeared in the *Journal* of the Boston Society of Medical Science (vol. v. p. 325). They are based upon observations made upon the larvæ of these mosquitoes by the author so long ago as 1879, and are illustrated by excellent figures of the larvæ and pupæ of Anopheles and Culex. These observations, it is believed, are the earliest which have been made on the first stages of the life-history of the two insects, and accord well with those recently recorded by other writers.

To the same author we are indebted for a report (from *Science*) of his Middleton Goldsmith lecture delivered before the New York Pathological Society on March 25. The subject is the embryological basis of pathology, the lecturer claiming that a scientific study of pathological phenomena is in a greater degree a superstructure upon embryology than it is upon anatomy. "The fundamental problems of pathology and embryology are," it is urged, "alike, not only in being problems of cell life, but also in being similar and even identical problems of cell life. Widely as the two sciences differ, they rest on a common foundation."

WE have received information of the occurrence of a considerable landslip in Danby Dale, a deep valley drained by a tributary of the Esk in the moorlands of East Yorkshire, about seven miles west of Egton. The region is one in which many landslips have from time to time occurred, owing to the undermining

and breaking away of the Dogger and Lower Estuarine Sandstones and Shales which overlie the Alum Shale. In the present instance, the slip appears to have affected about sixty acres of ground, while the fissure along which the subsidence took place extended for a distance of more than half a mile. The fall represented in the accompanying picture, reproduced from a photograph taken by Mr. George A. Macmillan, is about ten or twelve feet high. The fissure at the foot was filled with snow when the photograph was obtained.

A BEAUTIFUL coloured plate illustrating the remarkable resemblance presented to their inanimate surroundings by certain spiders forms the most attractive feature of vol. xxxi. part 2 of the *Travaux* of the Imperial Society of Naturalists of St. Petersburg. It accompanies an article, by Dr. W. A. Wagner, on colouring and mimicry among animals, of which there is a summary in German, the full text being in Russian. In several instances the spiders are represented on lichen-clad bark, the resemblance being most remarkable in the case of a species of Epeira on very dark bark shown in Fig. 7. Still more curious is a blue spider of the same genus nestling amid a rosette of azure lichen. Other examples show white or yellow spiders in flowers of similar colour, the resemblance being most complete in the case of a Vatia, whose yellow body is spotted with red to accord with a yellow and red flower. After tracing the gradual evolution of this type of "mimicry" among spiders from the dull-coloured to the bright-hued species, the author refers to certain well-known difficulties as to the origin of resemblances of this nature.

A LARGE Mycenæan *pithos* in the First Vase Room, British Museum, was inadvertently stated on p. 13, col. 1, line 6 from bottom, to have come from Ialysos in Rhodes. In reality it was brought from Knôssos itself by Mr. Minos Kalochairinos, who essayed several excavations at Kephala in years gone by.

WE learn, from the *Journal of Botany*, that a new society, to be called the International Botanical Association, is to be inaugurated at a meeting to be held in the botanical laboratory of the University of Geneva on August 7. The chief object of the Association will be "the foundation of a bibliographic periodical, criticising in a perfectly impartial manner all botanical publications. . . . The criticisms will, at the desire of the contributors, be published in English, French or German." The editor, who will be responsible to the Association for this absolute impartiality and the cyclopædic knowledge which it involves, will be Dr. J. P. Lotsy, of Wageningen, Holland; and the subscription to the Association, including the periodical, is not to exceed 25*s.* per annum.

THE first volume of a "Handbuch der systematischen Botanik," by Prof. R. R. v. Wettstein, has been published by Herr Franz Deuticke, Leipzig and Vienna. The chief object of the work is to present a view of the various forms of plants, with special reference to their phylogenetic development. The volume just received contains an account of the principles of systematic botany and of different plant systems, and a description of the characteristics of six great divisions of the plant kingdom, distinguished as follows:—myxophyta, schizophyta, zygophyta, euthallophyta, phaeophyta and rhodophyta. The cormophytes are reserved for treatment in the second volume, which will appear in the course of next year, when the two volumes will be noticed together.

THE additions to the Zoological Society's Gardens during the past week include three African Sheep (*Ovis aries*) from Bida Nigeria, a Bateleur Eagle (*Helotarsus ecaudatus*) from Zebba Nigeria, presented by Mr. Fanshawe Abadie; a Lion (*Felis leo*, ♂) from Africa, presented by Mr. Rowland Ward; a Chough (*Pyrrhocorax graculus*), British, presented by Mr. W. H. St. Quintin; a Black-pointed Teguexin (*Tupinambis nigropunctatus*) from South America, presented by Mr. G. P. Ogg; a Turkish Gecko (*Hemidactylus turicius*) from Western Asia, presented by Miss Kensington; six Ceylonese Terrapins (*Nicoria trijuga*), a Changeable Lizard (*Calotes versicolor*) from India, three Blue-tongued Cyclodus (*Tiliqua scincoides*), three Black and Yellow Cyclodus (*Tiliqua nigro-luteus*) from Australia, a Chained Snake (*Coluber catenifer*) from California, two Ten-lined Snakes (*Contia decemlineata*) from North America, two —— Snakes (*Contia rothi*) from Syria, four Lacertine Snakes (*Coelopeltis monspessulana*), four Vivacious Snakes *Tarbophis follax*), an Æsculapian Snake (*Coluber longissimus*), a Dahl's Snake (*Zamenis dahli*), two Dark Green Snakes (*Zamenis gemonensis*), a Common Snake (*Tropidonotus natrix*, var.) two Glass Snakes (*Ophiosaurus apus*), South European, two —— Ground Snakes (*Typhlops vermicularis*) from Asia Minor, a Black-necked Stork (*Xenorhynchus australis*) from Malacca, deposited; two Smews (*Mergus albellus*), a Velvet Scoter (*Ædemia fusca*), four Wigeon (*Mareca penelope*), European, purchased.

OUR ASTRONOMICAL COLUMN.

COMET *a* (1901).—A further telegram concerning the new comet has been received from Kiel announcing its observation at Arequipa, in Peru, on May 2, at 6h. 48·6m. p.m. Its position then was

$$\text{R.A.} = 3\text{h. } 30\text{m.}$$
$$\text{Decl.} = -1^\circ\ 0'.$$

A later telegram gives particulars of another observation at the Cape at the position

$$\left.\begin{array}{l}\text{R.A.} = 3\text{h. } 54\text{m. } 29\text{s.}\\ \text{Decl.} = -0^\circ\ 18'\ 27''\end{array}\right\}\ 1901 \text{ May 4d. 6h. } 28{\cdot}8\text{m.}$$

Daily Motion in R.A. = + 14m.
,, ,, Decl. = + 13′.

It has been observed at Eastbourne by Mr. Chambers, who saw it about 3.0 a.m. on May 2. Reports in the daily Press also state its frequent observation at Melbourne and the Cape, but its motion is there stated to be north-westerly.

STELLAR PHOTOGRAPHY WITH A SIDEROSTAT.—Some little interest has been evinced during the past few months in connection with the practical elimination of the rotation of the field which occurs when a siderostat is used to follow the diurnal motion. In *Comptes rendus* (vol. cxxxii. pp. 931–932) Prof. Lippmann suggests a mechanical contrivance, to be attached to the slide carrying the photographic plate, which shall be so geared to the driving mechanism of the siderostat itself as to compensate for the rotation of field.

Prof. Cornu, in the same number, pp. 1013–1017, calls attention to a method he has previously recommended and which he thinks very good as regards mechanical efficiency. The essential factor is the employment of a universal joint, the angle between the component axes depending on the polar distance of the direction of the reflected beam. The plate holder is rotated by means of a subsidiary mechanism through the medium of the joint. He was led to the device by having to design a mechanism to represent a formula in connection with polarised light in isotropic and other media, this formula being of the same type as that showing the rotation of field of a siderostat.

From Prof. Cornu's suggestions M. Gautier constructed the necessary apparatus for this purpose, which is used with the 50-inch refractor shown at the Paris Exhibition of 1900.

FORMULÆ FOR VARIATION OF LATITUDE.—The observations of latitude made by Profs. Doolittle and Gratchof (*Astronomical Journal*, Nos. 490 and 495) lead Prof. S. C. Chandler to consider that they afford evidence of changes in the annual component of latitude variation; he therefore proposes to include such changes in the numerical theory, and gives formulæ and tables of reduction which may be used for such observations (*Astronomical Journal*, No. 495).

POSITION OF NOVA PERSEI.—Prof. E. C. Pickering gives, in the *Astronomische Nachrichten* (Bd. 155, No. 3706), the following mean position adopted from numerous measures with the transit circle at Harvard College Observatory:

$$\left.\begin{array}{l}\text{R.A.} = 3\text{h. } 24\text{m. } 28{\cdot}10\text{s.}\\ \text{Decl.} = +\ 43^\circ\ 33'\ 54''{\cdot}8\end{array}\right\}\ (1901{\cdot}0).$$

PHOTOGRAPHS OF THE ZODIACAL LIGHT.—In *Popular Astronomy* for April Mr. A. E. Douglass, of the Lowell Observatory at Flagstaff, Arizona, describes some successful photographs of the western zodiacal cone which he was fortunate enough to obtain on February 13 of this year.

The lens he employed was made in 1899 by Messrs. Alvan Clark and Sons especially for this purpose; its aperture is 0·9 inch, focus 1·8 inches, the intensity being thus 1:2.

Previous to this date many exposures had been made of an hour or more, but the short exposure tried on the 13th was most successful. It appears that when the zodiacal light is at its best, exposures of about eight minutes are ample; when not so clear, about thirty minutes should suffice. Glycin or hydroquinone were found most trustworthy for development, the former being especially free from any tendency to produce general fogging of the plate. Reproductions from three of the photographs taken at intervals of a few minutes accompany the paper. They all show some trace of condensation about the centre of the illuminated cone.

FOG FORMATIONS.

BRIEF reference has already been made (vol. lxiii. p. 161, December 13, 1900) to some interesting observations and photographs of fog made by Mr. A. G. McAdie on Mount Tamalpais, a little to the north of San Francisco. Several articles upon the subject have been contributed by Mr. McAdie to the U.S. *Monthly Weather Review*, and the particulars given below have been derived from one in the issue of November, 1900. We are fortunate in being able to reproduce one of Mr. McAdie's striking photographs of fog, through the courtesy of Prof. Cleveland Abbe.

Fog is very prevalent on the central coast of California, especially in the vicinity of the Bay of San Francisco. The topography of the district is remarkable, because of the close juxtaposition of ocean, bay, mountain and foothill. A valley, level as a table, 450 miles long and 50 miles wide, having afternoon temperatures of 100° or over, is connected by a narrow water passage with the Pacific Ocean, the mean temperature of the water in this locality being 55°. Thus within a distance of 50 miles in a horizontal direction there is frequently a difference of 50° in temperature, while in a vertical direction there is often a difference of 30° in an elevation of half a mile. High bluffs, ridges and headlands are at such an angle to the prevailing strong westerly surface air currents that an air stream is forced with increased velocity through the Golden Gate, and there must of necessity be considerable piling up of both air and water vapour at this point. The locality may indeed be considered as a natural laboratory, in which experiments connected with cloudy condensation of water vapour are daily wrought, and it is therefore of more than passing interest to the meteorologist.

Much faithful work has been done in physical laboratories on the behaviour of water vapour at varying volumes, pressures and temperatures. Regnault, Thomson, Broch, Aitken, Kiessling, R. von Helmholtz, Hertz, Rayleigh, von Bezold, Barus, Marvin and others have worked upon the change of state from vapour to liquid and from liquid to solid, and while many irregularities are noted in the behaviour of water vapour, the general problems of decreasing volumes and increasing pressures until condensation points are reached have been solved; and it is well understood that the vapour-liquid and liquid-solid condensations are in themselves but two phases in a chain of condensation phenomena. The problem of fog is therefore a limited one. It may be considered as a special case of cloud development, occurring in the first and second stages of Hertz, viz., the unsaturated and saturated stages. Condensation in the free air, as in these fog formations, takes place under conditions different from those obtaining in the laboratory. There are no fixed restraining walls, though the strongly stratified outlines suggest sharply limited air streams. Again, saturation as it occurs in free, constantly changing air and true adiabatic saturation are not identical. Saturation in the free air must be studied in disadvantageous circumstances, for the work must be done at a distance, with instruments neither sufficiently delicate nor accurate, and there is no control of conditions possible.

An attempt has been made at the Mount Tamalpais station to correlate the surface pressure conditions with fog. There are, however, many different types of fog. The conditions prevailing in winter, when tule fog, formed in the great valleys, drifts slowly seaward, are very different from those prevailing in summer, when the sea fog is carried inland. A typical pressure distribution accompanying sea fogs has been recognised. In general, a movement southward along the coast of an area of high pressure in summer means fresh northerly winds and high temperatures in the interior of the State, with brisk, westerly winds, laden with fog, on the coast.

Direct cooling by contact or radiation is shown by von Bezold to be more efficient as a cause of rainfall than cooling by mixture, but in the production of fog it is probable that cooling by mixture (except in the case of ground fogs) is the most important factor to be considered. It is to be noted that reverse pressures should also be studied, for perhaps a close watch upon the conditions prevailing when fog is rapidly dissipating might conversely throw light upon the order and relative importance of the three ways of cooling, viz., mixture, expansion and radiation.

Von Bezold's deductions may be thus summarised: More vapour condenses when a stream of air and vapour at low temperature impinges on a mass of warmer air than with reversed conditions. Ocean fogs, as a rule, form when cool air flows over warm, moist surfaces, but in the case under discussion, where the ocean surface temperature is 13° C. (55° F.) and the air temperature may reach 27° C. (80° F.), it is evident that the above does not hold. It is more probable that condensation is the result of the sharp temperature contrasts at the boundaries of certain air currents having different temperatures, humidities and velocities, and that the contours of the land play an important part in the originating and directing these air currents. The summer afternoon fogs of the San Francisco Bay region, then, are probably due to mixture more than radiation or expansion. The winter tule fogs of the Sacramento and San Joaquin valleys are probably pure types of radiation fog, where the process of cloud building is from the cooled ground upward. Occasionally in summer, when the warm air has been pumped out of the valleys and there is rapid radiation, ground fog forms. An illustration of this is given in the accompanying figure, where fog covers a number of valleys.

FIG. 1.—Lifted fog. Height above the ground, about 500 metres. View from U.S. Weather Bureau Observatory, Mount Tamalpais.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Prof. Townsend, the new Wykeham professor of physics, delivered an inaugural lecture at the Clarendon Laboratory on Friday, April 26, upon the recent developments of electro-optics.

Mr. N. V. Sidgwick, of Christ Church, has been elected to an official Fellowship in Natural Science (Chemistry) at Lincoln College.

Mr. A. S. Hunt has been elected to a research fellowship at Lincoln College in order to enable him to prosecute his researches upon Egyptian papyri.

The degree of D.Sc. has been conferred upon Prof. A. H. Church, F.R.S., in recognition of his contributions to chemical and mineralogical science.

No honorary degrees will be conferred at the Encænia this year.

Mr. J. L. Myres and Dr. H. R. Mill have been appointed examiners for the newly-instituted diploma in geography.

The following grants have been made from the Craven University Fund:—100*l*. to Mr. D. G. Hogarth to enable him to continue his researches in Crete; 80*l*. to Mr. T. Ashby towards the cost of publishing the results of his researches in the Campagna Romana.

Mr. J. Passmore Edwards has given to the University the sum of 1675*l*. for the promotion of the study of English literature in its connection with the classical literatures of Greece and Rome.

Scholarships in natural science are advertised for Merton College, New College and non-collegiate students on June 18.

The new Radcliffe Library (presented to the University by the Draper's Company) and the new Pathological Laboratory are approaching completion. The latter and the pathological collections deposited in the University Museum will be, probably, placed under the charge of the reader in pathology, Dr. Ritchie.

The Junior Scientific Club held their 224th meeting on Wednesday, May 1. The papers read were: "Experiences in South African Hospitals," G. H. H. Almond (Hertford); "Organic Compounds of Phosphorus," S. P. Grundy (Balliol).

CAMBRIDGE.—The new Board of Agricultural Studies in their annual report give a favourable account of their first year's working. The number of students attending the special courses of instruction is thirty-nine. The experimental farm is in working order, and no less than thirty-two special experiments on crops, stock, manures, &c., are being conducted in various local stations at the instance of neighbouring county councils. The Board of Agriculture has this year made a grant of 1000*l*. in aid of the work of the department. The special examination in agricultural science for the B.A. degree, and the examinations for the University Diploma in Agriculture, begin on May 29 and extend to June 8.

The Vice-Chancellor will represent the University at the meeting of universities and learned societies in connection with the millenary commemoration of King Alfred the Great at Winchester, to be held this summer.

Prof. Allbutt and Prof. Sims Woodhead will represent the University at the British Congress on Tuberculosis to be held in London next July.

THE following external examiners, among others, have been appointed by the Council of the University of Birmingham. We notice with regret the absence of Astronomy from the subjects. Mathematics, Prof. Horace Lamb, F.R.S.; Physics, Prof. J. J. Thomson, F.R.S.; Chemistry, Prof. H. McLeod, F.R.S.; Zoology, Dr. S. F. Harmer, F.R.S.; Botany, Prof. Reynolds Green, F.R.S.; Geology, Prof. T. G. Bonney, F.R.S.; Anatomy, Prof. Alex. Macalister, F.R.S.; Physiology, Prof. J. G. McKendrick, F.R.S.; Pathology, Prof. G. Sims Woodhead; Medicine, Dr. Donald MacAlister; Public Health, Dr. George Reid.

THE Association of American Universities has recommended the fourteen universities in the United States to extend the Christmas vacation every year to include the first week in January, in order to permit scientific men to attend annual meetings then instead of in the summer. *Science* says: "Columbia University has the honourable distinction of being the first to adopt the important innovation, and has already changed its calendar for 1901–1902, setting free the week of January first for convocation purposes. It is expected that several other universities also will soon announce their adherence to the plan, and it is hoped that in a short time the majority of American and Canadian universities will adopt the recommendation under consideration."

THE Technical Education Board of the London County Council is offering for competition five senior county scholarships of the value of 60*l*. a year for three years, together with payment of tuition fees up to 30*l*. a year. The scholarships are open to young men and young women who are resident within the administrative County of London, and whose parents are in receipt of an income not exceeding 400*l*. a year; and they are tenable at Universities, University colleges, or technical colleges, whether in England or on the Continent. Candidates must be under twenty-two years of age on May 1, preference being given to those who are under nineteen years of age. In addition to the senior county scholarships the Board offers a limited number of free places at University College, King's College and Bedford College, London. The scholarships and grants of free places are awarded, not on the result of an examination, but on a consideration of the past record and achievements of the candidates. Application forms may be obtained from the secretary of the Technical Education Board, 116, St. Martin's Lane, W.C., to whom they should be returned not later than Monday, May 13.

THE Education Bill of the Government was introduced into the House of Commons on Tuesday, and was read a first time. The object of the Bill is to establish in every part of England and Wales a local education authority for the supervision of educational work of all grades; and it is hoped that this authority will ultimately have control over all schools within its area of influence, whether elementary, secondary or technical. The proposal of the Government is to make county and borough councils, acting through statutory committees, the educational authorities, and it is hoped that small counties will combine to form an education area. The new education committee will have no power of rating, but will merely spend the money placed at its disposal by the county council. This money will be derived chiefly from the local taxation receipts, so that the committees will become the successors of those at present responsible for technical instruction. A county council will also have the power of levying a rate, limited to 2*d*., either upon the whole county or upon any part of it for which it might be desirable to make provision, and the sum so raised will be entrusted to the education committee. School Boards and School Board rates are not touched by the Bill, but their ultimate absorption by the new educational authorities is contemplated.

THE Report of the U.S. Commissioner of Education for the year 1898–99 has been received. Much of this bulky volume is taken up with tables referring to the condition and progress of various branches of education, but there are also a number of interesting articles and summaries. A detailed statistical account is given of the institutions for higher education in the United States. A table is given showing the number of students in higher education to every million persons in the United States. In the year 1872 there were 852 of such students to 1,000,000 people, and in 1898–99 the proportion had risen to 1874 college students per million. In the year 1898–99 the total number of students in collegiate, graduate and professional departments of institutions for higher education and in professional schools was 147,164, of which 43,913 were enrolled as professional students in law, medicine and theology, leaving 103,251 students reported as pursuing studies in the liberal arts and applied science. The number of degrees conferred on men after passing through a recognised course was 10,794, and on women 4293. The total value of property possessed by institutions for higher education amounted to more than seventy million pounds. The endowment funds amounted to thirty-one million pounds, and the remainder represented the value of grounds, buildings, &c., used for instruction and research. The total income for the year covered by the report, excluding benefactions, amounted to about six million pounds. The gifts and bequests reported as having been received during the year reached the magnificent total of nearly five million pounds.

WE are glad to notice another movement for the extension of facilities for higher education. A short time ago a council was formed to consider the possibility of establishing a University College for North Staffordshire, and to promote interest in the educational needs of the district. The executive committee now report that the chairman of the council, Mr. Alfred S. Bolton, has purchased, as a site for the College, about three acres of land in a good position at Stoke-on-Trent, and has thus given generous aid to the educational cause of North Staffordshire. Principal Oliver Lodge has become a vice-president of the council in order to show that the scheme has the sympathy and good wishes of the University of Birmingham. It was pointed out by the committee which first started the inquiry into higher education in North Staffordshire that "The nature of the local industries demands special scientific instruction of a more systematic and thorough character than is at present provided anywhere in the district, and foreign competition by nations recognising the practical advantages of such instruction will prove disastrous to the district if the matter is continually neglected." The district is at present remarkably deficient in opportunities for higher education. With a population approaching half a million within easy reach of the centre, there is no institution where young people who have left the secondary school can obtain higher instruction nearer than Manchester (thirty-seven miles) or Birmingham (forty-five miles). Evidently there is room for further provision of educational facilities by the establishment of an institution of the rank of a University College; and it is satisfactory to know that another locality is being aroused to a sense of its educational deficiencies.

SCIENTIFIC SERIAL.

Bulletin of the American Mathematical Society, April, 1901.—Prof. F. N. Cole opens with an account of the proceedings at the February meeting of the Society in New York City, and, in addition to the titles of the nineteen papers communicated, gives an abstract of several of them. Three of the papers are printed. Their titles are: (1) Green's functions in space of one dimension, by Prof. M. Bôcher. The results arrived at are given, but the proofs and further developments are reserved; (2) Possible triply asymptotic systems of surfaces, by Dr. L. P. Eisenhart. This supplements a note by the author, in the January *Bulletin*, entitled, "A demonstration of the impossibility of a triply asymptotic system of surfaces." Instead of the general negation previously given, the author now gives the qualified one: The only triple systems of surfaces cutting mutually in the real asymptotic lines of these surfaces are composed of properly associated families of hyperboloids of one sheet and hyperbolic paraboloids; (3) Note on Hamilton's determination of irrational numbers, by Dr. H. E. Hawkes. The purpose of the note is to call attention to Hamilton's use of the partition (Schnitt) in his definition of certain irrational numbers (*Trans.* of the R. Irish Academy, vol. xvii. 1837, p. 293).—On a system of plane curves having factorable parallels, by Dr. V. Snyder, was read before the December meeting of the Society. The type of scrolls contained in a linear congruence, and having factorable asymptotic lines, gives rise to a class of plane curves whose parallels have a similar property (cf. a paper by the author, in the *American Journal of Mathematics*, vol. xxiii., on a special form of annular surface). Mr. Bromwich gives a very useful analysis of Dr. P. Muth's "Theorie und Anwendung der Elementartheiler" (1899, xvi. and 236 pp.), and hopes that the book may induce its readers to take up the special part of invariant theory treated in it. Mr. Bromwich has done good work in this direction (see *Proc.* of London Math. Soc. vol. xxxii. 1900, p. 98), where he gives a list of papers on the subject.—Short notices follow of Dr. R. Fricke's "Kurzgefasste Vorlesungen über Verschiedene Gebiete der höheren Mathematik, mit Berüchsichtigung der Anwendungen" (1900), and Dr. R. Böger's "Ebene Geometrie der Lage" (1900), both by Prof. H. S. White.—The notes are very copious and interesting, giving account of the courses of lectures in the Continental and home Universities, and the usual new publications close the number.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 28.—"A Preliminary Account of the Development of the Free-swimming Nauplius of *Leptodora hyalina* (Lillj.)." By Ernest Warren, D.Sc. Communicated by Prof. Weldon, F.R.S.

March 14.—"On the Preparation of Large Quantities of Tellurium." By Edward Matthey, A.R.S.M. Communicated by Sir George Stokes, Bart., F.R.S.

March 28.—"On the Enhanced Lines in the Spectrum of the Chromosphere." By Sir Norman Lockyer, K.C.B., F.R.S., and F. E. Baxandall, A.R.C.S.

In the recently published account (*Ast. Phys. Journ.* vol. xii. p. 307, 1900) of the spectroscopic results obtained by members of the expedition from the Yerkes Observatory during the solar eclipse of May 28, 1900, Prof. Frost claims to have established a close relationship between the bright lines in his eclipse spectra and the stronger lines of the Fraunhofer spectrum, and states that "61 per cent. of the latter were measured as bright on the plates."

He also states that "these plates give no evidence of any relationship between the bright lines and the 'enhanced' lines, or lines distinctly more intense in the spark than in the arc spectrum, although Sir Norman Lockyer has attached much significance to a supposed connection between them." He quotes specially the cases of titanium and iron lines, and of 48 enhanced lines of the former element acknowledges that 29—or 60 per cent.—correspond with lines in his eclipse spectra

The authors of the present paper show that if a difference of 0·3 tenth-metres be allowed between the wave-length of an eclipse line and that of the corresponding metallic line (and in some cases Prof. Frost accepts a difference of 0·35 or more between his adopted wave-length and Rowland's wave-length of the corresponding Fraunhofer line), there are 38 of the 48 enhanced titanium lines—or 80 per cent.—which have corresponding lines in the eclipse spectra, thus showing a closer relationship between the enhanced lines of titanium and the eclipse lines than that claimed by Prof. Frost between the latter and the stronger of the Fraunhofer lines.

To show the difference in behaviour in the eclipse spectra of the enhanced and unenhanced lines, several tables have been compiled. The first contains all the Fraunhofer lines in the region covered by Frost's eclipse spectra which have an intensity of 2 or greater, and which Rowland has ascribed to titanium only. These are 53 in number, 20 are enhanced lines and 33 are not. The comparison table indicates that 19 of the 20 enhanced lines have corresponding lines (nearly all prominent) in the eclipse spectra, the remaining one being probably masked by $H\gamma$. Of the 33 unenhanced lines, 23—or 70 per cent.—do not correspond with eclipse lines. Of the nine eclipse lines which do agree in position with unenhanced titanium lines, three are nearly certainly due to other metals, and the remainder are lines of insignificant intensity.

The second table gives the enhanced lines of titanium which are recorded by Hasselberg in the arc spectrum, and a comparison is made with Frost's eclipse lines. This table shows that though the "arc" intensities of the enhanced lines vary from 2 to 7 (max. = 8), they have nearly all corresponding lines in the eclipse spectra, the majority of the latter being quite prominent.

The third table contains all the strongest lines (Int. 7 and 8) in Hasselberg's list of arc lines which are unenhanced. It is shown that only 7 out of 20 have corresponding eclipse lines. To three of these Frost gives no origin, to the others he gives compound origins, three of them involving titanium. In no case is the eclipse line as strong as the majority of those which are the representatives of the enhanced lines.

In the case of iron a similar analysis is given, but only over a limited region of the spectrum (λ 4500 to λ 4600) owing to the great number of lines in the iron spectrum. The same results are arrived at, viz., that the enhanced lines, though insignificant in the iron spectrum so far as intrinsic intensity is concerned, are, in the main, represented in the eclipse spectra by lines of abnormal intensity, whereas many of the stronger iron lines are either not represented at all, or only by weak lines.

"On the Arc Spectrum of Vanadium." By Sir Norman Lockyer, K.C.B., F.R.S., and F. E. Baxandall, A.R.C.S.

In this paper the authors give a list of lines in the arc spectrum of vanadium which have been measured from photographs taken at Kensington with a Rowland concave grating of 21½ feet focus and 14,438 lines to the inch. The region of the spectrum investigated extends from λ 3887 to λ 4932. The sources of the spectrum were (1) vanadium chloride, and (2) a pure sample of vanadium oxide supplied by Sir Henry Roscoe. These were volatilised in the arc between poles of the purest silver obtainable, and which were furnished by Sir W. C. Roberts-Austen.

The lines are compared with those published previously by Rowland (*Ast. Phys. Journ.* vol. vii. p. 273, 1898) and Hasselberg (*Svenska-Vetenskaps. Akad. Handl.* vol. xxxii. No. 2, 1899). The three records contain many lines in common, but there are also many differences between any two of them. The lines special to any one list have been analysed with the object of either properly establishing their claim to be accepted as true vanadium lines, or possibly tracing them to their true origin. Lines in the Kensington spectra which are due to impurities have been eliminated, as far as possible, by comparing the vanadium spectrum directly with those of forty-three other elements. They are twenty-nine in number, and are traces of the strongest lines only of Fe, Mn, Cr, Co, Ca, Al, Sr and Ag.

Forty-four lines occur in Rowland's list only; thirteen of these have been traced with certainty to impurities of Ca, Mn, Al, Pb or Sr. No origin other than vanadium has been found for the remainder. A list of lines is given which Rowland has previously identified with solar lines, but which, for some reason or other, are missing from his latest list of vanadium lines.

There are 194 lines which occur in the Kensington list only. No other origin has been found for them from a comparison of the vanadium spectrum with those of the forty-three metals which have been photographed on the same scale. As they appear both in the spectrum of the chloride and oxide they are probably genuine vanadium lines.

"The Growth of Magnetism in Iron under Alternating Magnetic Force." By Ernest Wilson. Communicated by Prof. J. M. Thomson, F.R.S.

The subject of the shielding effects of induced currents due to changes of magnetic induction in plates of iron has been dealt with theoretically by Profs. J. J. Thomson (*Electrician*, vol. xxviii. p. 599) and J. A. Ewing (*Electrician*, vol. xxviii. p. 631). The same subject has been attacked by experiment in the case of iron cylinders (*Phil. Trans.* R.S. A vol. clxxxvi., 1895, pp. 93–121, and *Journal* Inst. Elec. Engineers, vol. xxiv. p. 195), and the object of the present paper was to carry out further experiments with alternating magnetic force.

The magnet consists of a solid iron cylinder 12 inches in diameter and 18 inches long, around which the magnetising coil is wound. The magnet circuit is completed by means of a ring concentric with the cylinder and a circular slab of iron at each end.

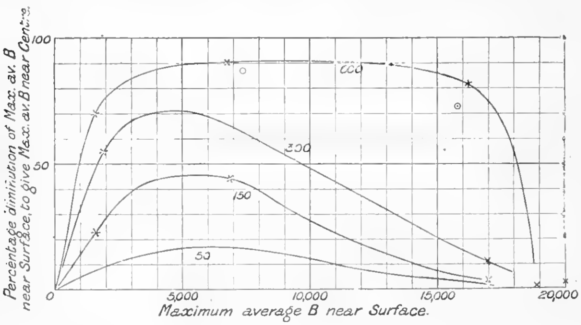

FIG. 1.

In order that changes of magnetism may occur at the centre of the cylinder it was necessary to employ alternating currents of long periodic time. Such times vary from 2·5 to 10 minutes in the experiments. It would be difficult to obtain such currents by means of electro-magnetic apparatus. A liquid reverser consisting of copper plates in dilute $CuSO_4$ solution was employed and gave satisfactory results.

For the purpose of observing the changes of magnetic induction at different points of the cylinder a series of holes were drilled in a plane perpendicular to the axis and half way along its length. Insulated copper wires were then threaded through these holes in such manner that each circuit enclosed an element of the cross-sectional area of the cylinder. Four such elements were enclosed between the centre and the circumference, and a fifth coil was wound completely round the cylinder, as it was required to take account of the average change of induction over the whole area. In the circuit of each of these five coils was placed a dead-beat galvanometer, the deflection of which enabled the E.M.F. to be observed. The epoch for the simultaneous observations of E.M.F. as well as the current in the magnetising coil was determined by the operator at the reverser counting seconds aloud. The E.M.F. curves were ultimately plotted in terms of time and integrated.

Before dealing with the experiments it may be stated that the results obtained are applicable to cylinders of other diameter than 12 inches. Similar electric and magnetic events will happen in cylinders of different diameters, but at times varying inversely as the square of their linear dimensions. Thus a periodic time of 10 minutes with the 12-inch cylinder corresponds to a frequency of 150 periods per second with a wire 1 mm. diameter.

Two variables have been dealt with, namely the frequency of the magnetising force H, due to the current turns in the copper coils of the magnet, and its amplitude. The figure gives one set of results obtained at 15° C. Each curve refers to a definite periodic time, and the number near it gives the frequency for a wire 1 mm. in diameter. The point of interest is that for a given frequency when the limits of the induction density, B, at the surface, are small, that is, the average permeability is small, the limits of B at the centre of the cylinder do not differ greatly from those at the surface. With larger limits of B at the surface, corresponding to a large average permeability, the limits of B at the centre are very much smaller than at the surface. Finally, when the limits of B at the surface are great, corresponding to a small average permeability, the limits of B at the centre are again more nearly equal to those at the surface.

Referring to the average induction over the whole core, that is, taking account of phase displacement as well as variation in amplitude, it may be stated that as the limits of B at the surface increase from zero, the maximum average B over the whole area grows less than B at the surface and then more nearly approximates to it. The curves are similar to those in Fig. 1, but the percentage diminution for a given frequency and a given value of B at the surface is not so great.

The magnet was heated to 53° C. and the effect was to tend to equalise the limits of B over the whole core. In the figure the points ⊙ were obtained when the magnet was at this temperature. The same maximum average B over the whole core is obtained with slightly less amplitude of magnetising force. On account of a greater phase displacement of the change of induction as the centre is approached, the maximum average B over the whole section is not greatly altered for a given maximum value of B at the surface.

Chemical Society, April 18.—Prof. Emerson Reynolds, president, in the chair.—The following papers were read:—Action of alkyl haloids on aldoximes and ketoximes. Part 2. Alkylated oximes and isoximes and the constitution of aliphatic oximes, by W. R. Dunstan and E. Goulding.—The supposed existence of two isomeric triethyloxamines, by W. R. Dunstan and E. Goulding.—Nitrocamphene, aminocamphene and hydroxycamphene, by M. O. Forster. On treating 1:1-bromonitrocamphane with silver nitrate, 1-nitrocamphene,

$$C_8H_{14}<\begin{matrix}CH\\ \|\\ C.NO_2\end{matrix},$$

is produced, and on reduction gives the corresponding 1-aminocamphene, $C_8H_{14}<\begin{matrix}CH\\ \\ C.NH_2\end{matrix}$. On heating the sulphate of this base with potassium nitrite it is converted into 1-hydroxycamphene, $C_8H_{14}<\begin{matrix}CH\\ \|\\ C.OH\end{matrix}$. This substance is of importance as being the enolic isomeride of ordinary camphor, into which it is converted by warm mineral acids.—A contribution to the chemistry of the triazoles, by G. Young and W. H. Oates. The authors discuss the possibility of isomerism in the triazole series as compared with the pyrazoles; they have prepared a number of substituted triazoles from the corresponding semicarbazones.—Researches on moorland waters. Part 2. On the origin of the combined chlorine, by W. Ackroyd. The author concludes that the common salt in the water of the Widdop reservoir in Yorkshire is derived from the winter rainfall.—Robinin, violaquercitrin and osyritrin, by A. G. Perkin. The composition $C_{33}H_{38}O_{20},8H_2O$ is now assigned to the glucoside robinin, which on hydrolysis yields a colouring matter, $C_{15}H_{10}O_6$, identical with campherol. Osyritrin has the composition

$$2C_{27}H_{28}O_{16}, H_2O,$$

and is identical with violaquercitrin.—Preparation of orthodimethoxybenzoin, and a new method of preparing salicylaldehyde methyl ether, by J. C. Irvine. An excellent yield of salicylaldehyde methyl ether is obtained by treating a mixture of salicylaldehyde and methyl iodide with dry silver oxide; it is converted into orthodimethoxybenzoin by potassium cyanate, and this is converted quantitatively into its methyl ether by methyl iodide and silver oxide.—Action of hydroxylamine on the anhydrides of bromonitrocamphane, by M. O. Forster.—On the estimation of cocaine and on diiodococaine hydriodide, by W. Garsed and J. N. Collie. On adding excess of decinormal iodine solution to a dilute solution of a cocaine salt, diiodococaine hydriodide, $C_{17}H_{21}NO_4,HI,I_2$, is precipitated and the excess of iodine may be determined by titration with thiosulphate solution.—Note on acetonylacetone, by T. Gray. The molecular refraction of acetonylacetone agrees with the value required for the ketonic formula.—Condensation of acetonylacetone with hydrazine hydrate, by T. Gray.—Preparation of synthetical glucosides, by H. Ryan and W. S. Mills. Acetochlorogalactose reacts with α-naphthol and potash yielding α-naphthylgalactoside, $C_6H_{11}O_5.O.C_{10}H_7$. Metacresylglucoside is similarly prepared from acetochloroglucose and metacresol.—The influence of cane sugar on the conductivities of solutions of potassium chloride, hydrogen chloride and potassium hydroxide; with evidence of salt formation in the last case, by C. J. Martin and O. Masson.—The aluminium-mercury couple. Part 3. Chlorination of aromatic hydrocarbons in presence of the couple. The constitution of the dichlorotoluenes, by J. B. Cohen and H. D. Dakin.—A modification of Gutzeit's test for arsenic, by E. Dowzard.—On the chemistry of *Nerium odorum*, by R. C. L. Bose. In addition to neriodorein and neriodorin, already known to exist in the plant, the author has extracted a new resin-like substance from the sweet-scented oleander, *Nerium odorum*; this has the composition $C_{21}H_{49}O_6$, and is named karabin.—Change and interaction in organic compounds, by A. Lapworth.—The mechanism of the Claisen reaction, by A. Lapworth.—A new series of di-mercuri-ammonium salts, Part 1, by P. C. Rây. Ammonia acts on mercuric nitrite giving a di-mercuri-ammonium nitrite of the composition

$$2NHg_2NO_2, H_2O.$$

This yields salts of the types $NHg_2Cl,4HCl$ and $2NHg_2Cl,H_2O$, with the halogen acids.

Royal Microscopical Society, April 17.—Mr. Wm. Carruthers, F.R.S., president, in the chair.—Mr. Enock gave a demonstration on the metamorphoses of one of the dragon flies, *Æschna cyanea*. In his endeavours to obtain a complete set of photographs from life which would show every stage in the metamorphoses of the nymph of the dragon fly he had taken over 1000 photographs before he was successful; those he was about to show were taken from the same individual and recorded every stage of the process, which occupied a period of six hours only. Considerable patience and constant watching were required, as after the first indication of change was noticed the dragon fly might emerge at any time in the following three days, and when the process of emergence began it went on rapidly, so rapidly, in fact, that three photographs were taken within the space of six seconds. Mr. Enock then showed on the screen photographs of a nymph to illustrate the remarkable movements of the mask by which the insect was enabled to capture its prey. These were followed by a series of about thirty slides, illustrating every stage of the metamorphosis from the nymph to the perfect insect.—Mr. Nelson exhibited a slide of podura scales under polarised light.

Royal Meteorological Society, April 17.—Mr. W. H. Dines, president, in the chair.—Mr. W. Marriott read a paper on the special characteristics of the weather of March 1901. From March 1 to the 12th or 13th the temperature was slightly above the average, the prevailing winds being from the south-west and often strong in force. About the 13th a change set in, when north-easterly winds became predominant and low temperatures prevailed. This continued with increasing intensity until the 29th, the last two days of the month being nearly of average temperature. The most remarkable period of the month was the five days from the 25th to 29th, when the temperature was more than 10° below the average all over the country. The north-easterly winds were strong in force and particularly keen and dry. At the Greenwich Observatory the relative humidity was only 52 per cent. on the 26th and 54 per cent on the 27th. The only other instance during the past 54 years of as low a relative humidity in the month of March was on March 1, 1886. In consequence of this keen and cold weather, vegetation was at a standstill. Snow showers were frequent but not very heavy, except on the 20th in the south-west of England, when on Dartmoor nearly as much snow fell as in the great blizzard of March 1891; and on the 29th, when a very heavy fall of snow and rain occurred in the north-west of England and Wales. Although the death-rate was below the average, there was a considerable increase in the deaths due to diseases of the respiratory organs.—A paper by Mr. R. Strachan, on vapour tension in relation to wind, was also read.

Anthropological Institute, April 23.—Prof. A. C. Haddon, F.R.S., in the chair.—Specimens of Neolithic implements from the Wilts border of Berkshire were exhibited by Mr. L. J. Shirley.—Mr. Franklin White exhibited stone implements, pottery and silver ornaments from Central Rhodesia; he then read a paper on the ruins of Dhlo-Dhlo, or Mambo, illustrated by lantern slides, photographs and plans. The author gave a detailed description of the nature, dimensions, ornamentation and state of preservation of the ruins, and showed that the theories of the late Mr. Theodore Bent with regard to the Zimbabye ruins would not apply to the ruins of Dhlo-Dhlo, the orientation and other details depending mainly on the character of the ground.—Papers on the Baganda, by Rev. J. Roscoe, and on folktales of the New Hebrides, by Mr. S. H. Ray, were taken as read.

MANCHESTER.

Literary and Philosophical Society, April 23.—Prof. Horace Lamb, F.R.S., president, in the chair.—Dr. Elie Metchnikoff, Paris, was elected an honorary member of the society. Mr. Charles Bailey was elected president of the Society for the session 1901–2.—Prof. S. J. Hickson communicated two papers by Miss E. M. Pratt, upon a collection of Polychaeta from the Falkland Islands, and some notes on the bipolar theory of the distribution of marine organisms. In the first paper Miss Pratt described a small collection of Polychaeta collected in shallow water off the shores of the Falkland Islands. There are no new species, but considerable interest attaches to certain forms which are new to the southern hemisphere, amongst them being *Arenicola claparedii*, now recorded for the first time outside the northern temperate region. The second paper contained a review of the facts of zoology bearing upon the theory that the marine organisms found around the two poles of the earth have been derived from a common or universal fauna, which existed in the past history of the world, at a time when the seas were of a more uniform temperature. It was shown that the evidence in favour of the theory is increasing rapidly, and our knowledge of the details of anatomy of the north and south representative species reveals a closer relationship between them than might have been anticipated.

PARIS.

Academy of Sciences, April 29.—M. Fouqué in the chair.—On the mechanical compensation of the rotation of the optical field furnished by the siderostat and heliostat, by M. A. Cornu. The theoretical solutions of this problem given by Turner and by Lippmann have been anticipated practically by M. P. Gautier, who has devised a simple mechanism for moving the photographic plate with an angular compensating movement sufficiently precise to obtain a good negative with a short exposure (see p. 42).—On the use of oxygen in ascents at great heights, by M. L. Cailletet. A description of an apparatus by means of which liquid oxygen can be used by aëronauts. Its great practical service was demonstrated in a balloon ascent of 5500 metres.—On the stability of a system having a movement of rotation, by M. P. Duhem.—M. Zeiller was elected a member in the Section of Botany in the place of the late M. A. Chatin.—On a generalisation of a definite integral, by M. H. Lebesgue.—On the analytical integrals of differential equations of the first order in the neighbourhood of initial singular conditions, by M. Henri Dulac.—On the equations of certain groups, by M. de Seguier.—On the laws of Belgrand and the formulæ for the delivery of a water-course, by M. Edmond Maillet.—The isochores of ether from 1·0 to 1·85 c.c., by M. Edouard Mack. The experiments confirm the law of Amagat that at constant volume the pressure is a linear function of the temperature.—On the measurement of the period of electric oscillations by the rotating mirror, by M. L. Décombe. A discussion of the precision to be obtained by means of the rotating mirror method and a criticism of results previously published on the same subject by M. Tissot.—On the band spectrum of nitrogen in the oscillating spark, by M. G. A. Hemsalech. It is shown that the band spectrum obtained with the oscillating spark with certain metals is identical with the band spectrum of nitrogen at the negative pole.—The rapid measurement of surface tensions, by MM. Ph. A. Guye and L. Perrot. A study of the conditions under which the method of falling drops gives accurate results for the surface tension of liquids.—On the variation of composition of mineral waters and of spring waters as brought out with the aid of the electric conductivity, by M. P. Th. Muller. The composition of a water having been once determined chemically any variation of its composition from time to time can be most easily detected by determining its electrical conductivity.—On myrcenol and its composition, by M. Ph. Barbier. By studying the oxidation products of this substance it would appear to have the same constitution as that attributed to licareol by Tiemann, but as the physical and chemical properties of myrcenol are altogether distinct from those of licareol it is necessary to reconsider the formula attributed to the latter substance.—On ethyl nitroacetate, by M. A. Wahl. Since the substance obtained by the action of ammonia upon ethyl nitro-dimethylacrylate gave an ethyl nitroacetate which was not identical with the specimen obtained by M. de Forcrand, an attempt was made to prepare this compound by an independent method. The decomposition of ethyl nitromalonate by boiling with potash was finally found to give the compound sought for, which agreed in its properties with the ester previously prepared by the author, but differs from the nitroacetate of de Forcrand.—The preparation of the isomeric ortho-, meta- and para-nitrobenzoylcyanacetic esters and of orthonitrobenzoyl chloride, by M. Mavrojannis.—A new reaction of saccharin, by M. Alex. Leys.—On the migration of nitrogenous and ternary matters in annual plants, by M. G. André.—On the *Voandzou*, by M. Balland. An analysis of the seeds of this plant showed that the proportions of fat, nitrogenous material, starch and ash are exactly those required for human food. It is the first example of a natural product presenting the chemical characteristics of a perfect food.—Contribution to the microchemical examination of alkaloids, by M. M. E. Pozzi-Escot.—On the phenomena of histolysis and histogenesis accompanying the development of the endoparasitic Trematods of terrestrial mollusca, by MM. Vaney and A. Conte.—On the evolution of the blastodermic leaflets in the Nematods, by M. A. Conte.—On a new subfamily of marine Hemiptera, the *Hermatobatinae*, by MM. H. Coutière and J. Martin.—Researches on the physical constants which influence the electrical stimulation of the nerve, by M. Georges Weiss.—The direct measurement of the wave-length in a nerve following short electrical stimulations, by M. Aug. Charpentier.—Some remarks on the otoliths of the frog, by M. Marage.—The influence of the sterilisation of the medium, the air respired and the food absorbed upon the animal organism, by MM. Charrin and Guillemonat. The comparative experiments upon guinea-pigs would tend to show that the absence of bacteria in the air and food is distinctly prejudicial to the animal, which loses its vitality and resisting power to disease.

DIARY OF SOCIETIES.

THURSDAY, MAY 9.

ROYAL SOCIETY, at 4.30.—Discussion of Special Report.

MATHEMATICAL SOCIETY, at 5.30.—(1) A Case of Algebraic Partitionment; (2) On the Series whose Terms are the Cubes and Higher Powers of the Binomial Coefficients: Major MacMahon, R.A., F.R.S.—A Property of Recurring Series: G. B. Mathews, F.R.S.—The Product of Two Spherical Surface Harmonic Functions: J. B. Dale

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Storage Batteries in Electric Power Stations, controlled by Reversible Boosters: J. S. Highfield.

IRON AND STEEL INSTITUTE, at 10.30.—Annual Meeting.

FRIDAY, MAY 10.

ROYAL INSTITUTION, at 9.—The Response of Inorganic Matter to Mechanical and Electrical Stimulus: Prof. J. C. Bose.

PHYSICAL SOCIETY, at 5.—Applications of Elastic Solids to Metrology: Dr. C. Chree, F.R.S.—The Thermal Properties of Isopentane compared with those of Normal Pentane: Prof. S. Young, F.R.S., and J. Rose-Innes.

Fenton and Miss Mildred Gostling.—The Preparation and Optical Inversion of Optically Active Nitrogen Compounds. dextro- and Lævo-α-benzylphenyl-allyl-methylammonium Salts: W. J. Pope and A. W. Harvey.

FRIDAY, MAY 17.

ROYAL INSTITUTION, at 9.—Turkish Kurdistan: Earl Percy.

SOCIETY OF ARTS, at 8.—Polyphase Electric Working: A. C. Eborall.

SATURDAY, MAY 18.

ROYAL INSTITUTION, at 3.—Rise of Civilisation in Egypt: Prof. W. M. Flinders Petrie.

CONTENTS.

THURSDAY, MAY 16, 1901.

THE SIGNIFICANCE AND SCOPE OF NATURAL SELECTION.

Ueber Bedeutung und Tragweite des Darwin'schen Selectionsprincips. Von L. Plate, Privatdozent an der Universität Berlin. Pp. 1–153. (Leipzig: W. Engelmann, 1900.)

THE great merit of this interesting and thorough piece of work is its explicit recognition of the principle of selection as an indispensable element in organic evolution. We are in some degree prepared for the author's attitude on this question by the last sentence of his preface, in which he asserts that the principle of selection affords at the present time the only scientific explanation of the harmony existing between the endowments of an organism, whether structural or functional, and its surrounding conditions. From this statement it might be supposed that the author not only holds selection to be an essential agent in organic evolution, but that he is also prepared to dispense with the Lamarckian factors, which have certainly been appealed to as furnishing an alternative or concurrent explanation of the same harmonious relations between organism and environment. Such, however, as will be seen later, is not the case.

Nothing could be better than the impartial and judicial spirit of the opening pages, in which the author moves methodically on from point to point, clearing the ground of misconceptions, and disposing conclusively of a long series of well-known but futile objections to the theory of natural selection. Presently he takes in hand the case of the superior oblique muscle of the orbit, and shows admirably how the difficulties disappear on reference to the facts of comparative anatomy. But at this point he lets fall an *obiter dictum* which, in view of his opening declaration, is somewhat startling. The development of a muscle-tendon, he thinks, may be explained as the consequence of a pull exercised in a certain direction through many generations. We are thus confronted with a re-entry of Lamarckism; and, reading on, we find abundant proof that Plate, so far from really holding that the phenomena of adaptation are only to be explained by selection, thinks it necessary to supplement that principle by the hereditary transmission of acquired characters. Thus the parachute-like membranes of the flying squirrels, *Galeopithecus*, flying lizards, and the like, are considered by him to have originated from a stimulus exercised by the outstretched limbs upon the skin of the sides of the body, the effects of which accumulated for many generations (p. 31). The ischial callosities of monkeys were produced by the sitting posture (p. 36). The loss of hair and development of blubber in the whales may be due to the direct action of water on the skin and subcutaneous connective tissue (pp. 111, 142). In short, the author leaves us no room to doubt that he believes in use-inheritance, and in the possibility of the transmission of characters however acquired.

On turning to the grounds for his belief, we find them stated as follows (p. 55):—(1) All or almost all of the somatic cells may be supposed to contain germ-plasm; this is made probable by the phenomena of regeneration. Moreover, the whole of the germ-plasm, whether of the somatic or genital cells, may be conceived of as forming a network whose nodes are situated in the nuclei of the different cells. A peripherally-started impulse would be propagated along such a network in all directions, and in this way a somatogenic character might become transmissible by descent. (2) Use-inheritance forms the simplest explanation of co-adaptation. (3) Many phenomena can only be understood by reference to orthogenesis, *i.e.*, the cumulative effect of a stimulus acting through many generations. (4) The gradual dwindling of rudimentary (vestigial) organs must be accounted for by inheritance of the effects of disuse.

Of these, the first is mainly speculative; moreover, were the initial assumptions granted, it would still be far from clearing up the actual mode of the supposed transmission. Two of the others have no doubt been felt as difficulties by some of the upholders of natural selection, and have already been pressed home by Herbert Spencer; but there are other ways of accounting for these and similar phenomena which seem more satisfactory than the recourse to Lamarckians' explanations. Plate very candidly admits that there is at present no direct proof of the transmission of acquired characters, and it is unfortunate that he burdens his argument for selection with the unnecessary weight of an unproved and improbable hypothesis. His real reason for declining to rank himself with the anti-Lamarckian is probably the difficulty that he finds, in common with many others, in assigning selection-value to the early stages of variation. But, as Wallace and others have shown, when the actual variations come to be fairly examined, it appears that ample material for selection exists from the outset. It is worthy of note that Plate himself, in discussing Cunningham's strictures on Weldon's experiments with crabs, admits that the latter has virtually shown the selection-value of slight differences of structure.

A large portion of the treatise is devoted to the subject of sexual selection. An excellent classification of secondary sexual characters is given, and the whole question is treated on broad and generally rational lines. It is to be regretted, however, that the author, in emphasising the slenderness of the evidence for female choice that at present exists, has failed to do justice to the statements of some opponents. An instance of this occurs in the case of an observation of Poulton's, whom Plate represents as having watched the female of such a moth as *Saturnia carpini* resting motionless amidst a crowd of fluttering males, all of them most eager to pair, but unable to do so until the female, in some way imperceptible to the observer, made her choice. Poulton's interpretation of the facts is somewhat curtly rejected, and the subject is dismissed. A reference, however, to the original account will show that the argument is inaccurately given. The moth specified is not *Saturnia carpini* or one of its allies, but the widely removed *Charaeas graminis*. On the other hand, Poulton expressly says that the female of *Saturnia carpini* "in its present condition is certainly passive, and probably always accepts the attention of the first male to arrive." The slip would matter little were it not that it has the effect of obscuring Poulton's argument, which rests on the observed facts that the females of some moths (as *Saturnia carpini* and *Orgyia antiqua*) accept the first male that arrives, while those of others (as *Charaeas graminis*) allow a period of competitive courtship; and, further, that as a rule moths with bright colours belong—or at a former period did belong—to the latter group rather than to the former.

Plate's own view as to female choice is that it is exercised only as between pairing and not pairing. There is, he thinks, plenty of evidence as to success or failure of incitements employed by the male, but little or none of choice by the female between individual suitors. The distinction seems rather delicate. A would-be pairer may fail from want of sufficient power to charm the female; but rejection implies choice, and if competitive incitement *does* take place, as Plate seems to allow, whether simultaneously or successively, how does this differ from sexual selection in Darwin's sense?

On the subject of "sports," the author is no doubt right in contending that they have little or no bearing on the question of species-formation. But before unreservedly asserting that they must tend to be swamped by intercrossing with the parent species, he would have done well to examine the evidence brought forward by Standfuss and others in support of the position that the crossing of an aberration with the parent form may often result, not in the production of intermediate types, but in the sharp cleavage of the offspring into two groups, each resembling one of the parents and not the other. If these observations and experiments are to be relied on, they imply the theoretical possibility of a sport, supposing it to be selected, eventually displacing the parent form; and, indeed, there is little doubt that under domestication something very much like this has actually occurred.

The treatment of adaptation is in many respects excellent. Kallima, the well-known Indian genus of leaf-like butterflies, is once more brought to the front and used as a conclusive instance of selection, furnishing also a good *reductio ad absurdum* of the "photographic" theory. But the author introduces a needless confusion by his method of handling the subject of "direct" and "indirect" adaptation. The former, he says, is repudiated by the "School of so-called Neo-Darwinians," of whom he specifies Weismann, Wallace and Spengel. It is certainly repudiated by them in the sense that they see no evidence for the "transmission of modifications due to individual plasticity," to use Lloyd Morgan's expression. But a distinction much more in accordance with the facts is that between "variable" and "invariable" adaptations. In the former are included such cases of individual assimilation in colour to surrounding conditions as have been principally made known, in the instance of caterpillars and chrysalises, by the labours of a "Neo-Darwinian." These adaptations are apparently "direct" in the sense that they mark a reaction of the individual to its own environment, but not in the sense that they are in any way actually produced by that environment. In common with all other cases of adaptation, whether variable or invariable, they are ultimately the result of a process of selection. The sensitive species is selected, not because it is green or because it is brown, but because in response to the appropriate conditions it is capable of becoming either one or the other. Plate's inclusion of Haeckel, Lloyd Morgan, Osborn and Henslow in the same category of believers in "direct adaptation," together with his criticism of Baldwin on an earlier page, serves to show that he has imperfectly grasped the point at issue. What we hold to be the true doctrine has been excellently expressed by Spengel in a passage quoted by Plate with disapproval (p. 141).

Though we have felt bound to express dissent on many points, we must not be taken as undervaluing Plate's labours. On the contrary, we have formed a high opinion of his knowledge, industry and argumentative power. As a champion of the indispensability of natural selection he has done excellent service, and it is only to be regretted that in adopting this illuminating principle he has failed to set himself free from the bonds of what seems to us a fanciful and unnecessary adjunct. F. A. D.

A TEXT-BOOK OF ELECTRICITY.

Deschanel's Natural Philosophy. III. *Electricity.* By J. D. Everett. Pp. xii + 358. (London: Blackie and Son, Ltd., 1901.)

PROF. EVERETT'S "Deschanel" is too well known to need commendation, and the new edition which is now before us has the many merits of its predecessors. The account it gives of fundamental electrical phenomena is admirable, the descriptions of apparatus are clear and good, though at times slightly too concise, the printing is well arranged and accurate, and the illustrations are excellent. In places, it is true, we recognise old friends which have done duty somewhat too often.

At the same time, the task just now of writing a really satisfactory text-book of electricity is a most difficult one, and Prof. Everett's success is not complete.

"The work," he says in his preface, "is in the main new. Electrical theory has been revolutionised during the past few years; and great need exists for a text-book which shall present the subject in its present shape as a clear and connected whole without demanding on the part of the reader an exceptional amount of mathematical knowledge. This is the want which I have endeavoured to supply."

"The work is *in the main* new." Prof. Everett has hampered himself in his attempt to give a modern theory of electricity by retaining even that part of the old which he has kept; the result is somewhat of a patchwork. Thus, Maxwell's conceptions with regard to electric action in dielectrics are introduced as "a new chapter in electrostatics." What was wanted was not an additional chapter in an old book, but an elementary account of the fundamental phenomena of electrostatics, given in the language of Maxwell's theory.

The book commences with electrostatics, and of necessity the language used at first is that of the theory of action at a distance. A charged body attracts light bodies and repels other bodies similarly charged; the action of a gold leaf electroscope depends on the repulsion between the like charges of the leaves; the electrophorus is described as a means of obtaining electricity in small quantities, but no explanation is given in §30 of its action.

The idea of electric potential is introduced in chapter vi., the first of the chapters in large type. These, it is said, "will be found to contain a connected account of everything essential to a first course of modern electrical theory."

But in chapter vi. the definition of potential is a mathematical one. The distinction between scalar and vector quantities is drawn, and it is pointed out that in many cases the line integral of a vector between two points is independent of the path, and that in this case the vector is said to have a potential, the value of the line integral being the difference of the potentials at the two points which are taken as the extremities of the path.

A number of mathematical propositions connected with the theory of potential are then proved or illustrated in a very interesting way; but the application of the theory to the fundamental facts discussed in the earlier chapters is hardly attempted.

The beginner might be given some idea of the nature of potential without being asked to grasp the meaning of a line integral. Faraday's and Maxwell's notions as to the tension along the lines of force and the pressure perpendicular to them which occurs in a dielectric medium may be used, without the introduction of symbols, to explain the simple attractions and repulsions described in the earlier chapters; the link between the ancient observations and the modern theory is wanting, and the loss to the reader is very marked.

The same want is illustrated in the two following chapters. The quantity K, the specific inductive capacity of a medium, is defined in the usual way in §70, and a footnote tells us "it is identical with the permittivity or dielectric co-efficient K." This statement is repeated in the next chapter, on electric action in dielectrics, but the author does not explicitly establish the connection; a few words at the end of §86 would do it, the words, however, are wanting.

Or again, K is defined as the ratio of the polarisation, or the intensity of the electric displacement, to the force. Now the force has a perfectly definite meaning, and the inductance K can be defined in unambiguous terms; why then make it depend on "a peculiar distortion called electrical displacement" which is "roughly represented by supposing every tube of force to be divided into cells by elastic membranes firmly attached to the tube, these cells being completely filled with incompressible liquid. The distortion does not displace the sides of the tube, but it displaces the liquid a little way along the tube, in the direction of the force F, further displacement being prevented by the elastic resistance of the membranes."

The inductance of a dielectric is too important a physical quantity to be defined in terms of something which can only be explained by an incomplete analogy; it is surely better to say that the force between two given charges is found to depend on the medium in which they are placed, so that the complete law of force is $F = ee^1/Kr^2$, where K is a constant for a given medium, and is known as the permittivity or inductance of the medium. Then the statements in §80 as to the modification of fundamental formulæ follow naturally; as it is, they seem to the reader to depend on the analogy between the flow of a liquid and electric displacement, and not to rest on an experimental basis.

The earlier chapters on magnetism are clear and good, §148, giving the reason why a bar of soft iron sets parallel to the lines of force, may be specially commended. Chapter xiii. gives a useful development of magnetic theory; the proof of the relation, however, between B and H, §158, might be given in fuller detail, and a reference to §83 as well as to §90 would not be misplaced.

The rest of the book is taken up with the theory of electric currents and electro-magnetism, and can, on the whole, be warmly commended. The description of instruments, ammeters, voltmeters and the like is brought up to date. At times, possibly, almost too much is attempted for the space available, *e.g.*, in the very condensed account of the ballistic galvanometer in §200. Again, some preliminary account of a voltaic cell is needed before §213, which begins "In a circuit consisting of a battery of four similar cells."

In places the book would be improved by a more distinct reference to the fundamental experiments on which the various laws are based. Thus in chapter xix., after a reference to a statement as to the force exerted on a wire carrying a current in a magnetic field, we pass on to "two fundamental formulæ." These formulæ give the electrical and mechanical forces on a conductor carrying a current when in a magnetic field, and various important deductions are drawn from them in an admirable manner in the following paragraphs. But we miss any clear indication of the method by which these two fundamental formulæ are deduced from experimental results.

The chapter on dynamos is specially good; there is sufficient detail to enable the student to grasp the principles which underlie the action of the various forms, while at the same time the book is not overburdened with accounts of small differences of construction which, though they are of great importance to the student of dynamo design, have no place in a general text-book.

Enough, perhaps, has been said to show the value of the book. Prof. Everett has rendered a real service to his readers by his new edition; the book is one which is sure to become popular and to be valued alike by teacher and by student.

AN ESSAY IN CRITICAL BIBLIOGRAPHY.

The Periodic Classification and the Problem of Chemical Evolution. By G. Rudorf. Pp. xvi + 228. (London: Whittaker and Co., 1900.) Price 4*s*. 6*d*.

THE object of this work, as stated by the author in his preface, is one which should command hearty approval. The author aims at presenting a summary of the work done and the speculations advanced in the particular field indicated in the title. The publication of such summaries has long been customary in Germany, and it is to be hoped that the custom may become more common in England. Most text-books published in this country suffer from one or other of two defects. Either they are very elementary in scope and wholly didactic in treatment, or they are diffuse in treatment and of unmanageable size. This work certainly does not fall under either condemnation. It deals with a difficult subject, and is rather suggestive and argumentative than didactic. On the other hand, it is neither unreasonably long nor over-elaborate in treatment. Indeed, it sometimes errs in the other direction.

The first part deals with the history of the periodic law and the experimental evidence for periodic variation of properties with atomic weight, and in many cases information is given in so condensed a form that it must be well-nigh unintelligible to those whom the author has avowedly sought to benefit, students "who may not have either time or opportunity to refer to the original literature." This is particularly the case in the portions which deal with various attempts to formulate numerical relations between the atomic weights.

In the second part of the book the author seeks to establish the theses (1) that "the elements have a fixed, definite structure," (2) that "the elements are complexes of some primary material," and (3) that this primary material is hydrogen. Dealing with the first of these, the author gives a sketch of the evidence to be derived from stereo-chemistry which is so short that it amounts to little more than a series of references, but which is useful so far as it goes. The inference that the elements in any one group of Mendeléeff's table should all have the same shaped atom is somewhat sweeping, but is opportunely supported by the recent work of Messrs. Pope and Peachey on optically active tin compounds.

As to the second, the arguments which have been advanced in support of it are fairly well presented, but the author misses altogether the point that the "meta elements" of Crookes supply an essential link in the chain of reasoning by which it is possible to reconcile the discontinuity implied in the atomic theory and the periodic law with the continuity predicated in the hypothesis of protyle.

In support of the third proposition, that protyle and hydrogen are one, the author adduces several well-known arguments, many of which, particularly those based on stellar spectroscopy, are fairly well stated and of acknowledged cogency. But his answer to the obvious difficulty that the atomic weights are not whole multiples of that of hydrogen is, though not unfamiliar, decidedly unsatisfactory. That the third law of motion may be valid only where molar masses are concerned is, of course, a legitimate suggestion, but it is a suggestion in support of which no fact save the difficulty under discussion can at present be adduced. It is surely as reasonable to regard that difficulty as fatal to the hypothesis that hydrogen is protyle as to find in it a reason for doubting the universal applicability of the third law of motion.

The author, moreover, minimises in an extraordinary way the remarkable evidence which has been accumulated through the study of ions produced in gases by the action of Röntgen rays, Becquerel rays and ultraviolet light. "The portion of this book dealing with chemical evolution was," we are told, "submitted to Sir Norman Lockyer," and some of the notes which he made upon it are prefixed to the volume. In them attention is drawn, more than once, to the importance of this work on gaseous ions in relation to the problem under discussion. The author does, it is true, add to these notes a brief abstract of one of Prof. J. J. Thomson's papers. But the matter is far too important to be thus disposed of in a prefatory note. The fact that the negative ion in gases has a mass which is very small compared with that of an atom of hydrogen is well established, not only by the researches which the author quotes, but by other and later work of Prof. Thomson on the negatively charged particles given off when ultraviolet light falls on a zinc plate, and also by the experiments of MM. Becquerel and Curie on the radiations emitted by radium. The conclusions to be drawn from these researches, while they are in full accord with the view that the elementary atoms of the chemist are themselves complex aggregates of yet smaller particles, require that these particles should be of an order of magnitude so far inferior to that of a hydrogen atom that they cannot fairly be described as "hydrogen" at all.

If, as may be expected, a second edition of the work is called for, it is to be hoped that the author will take the opportunity of incorporating these results, and with them the still later work of Prof. Townsend on the variations of conductivity in rarefied gases, the results of which also emphasise in a remarkable way the extreme smallness of the negative ions.

In conclusion, it must be said that the author has occasionally suffered unduly at the hands of his printer. There are a number of ordinary misprints which might be expected in a work of the kind, but a worse piece of printing than that of the numerical expressions illustrating the summary of Dr. Dulk's paper (on p. 71) it would surely be difficult to find.

A. F. W.

OUR BOOK SHELF.

Der Gesang der Vögel. Von Dr. Valentin Häcker. Pp. 1+102. (Jena: Gustav Fischer, 1900.)

THIS is an exceedingly interesting and useful contribution, and may be regarded as perhaps the most accurate and complete summary of this subject extant.

The author devotes the opening pages of his work to purely anatomical details, illustrated by numerous text-cuts representing voice organs of the passerine type. He introduces, for purposes of comparison, a short description and a figure of the tracheo-bronchial region of the reptile, the tortoise being selected as the most suitable.

The second chapter opens with a reminder that the variety of tone and range of vocal power depends largely on the modification of the upper ends of the bronchial tubes and the lower end of the syrinx. This is supported by a brief survey of the simpler types of syrinx ending in the very perfect voice organ of the Passeres, with its complicated muscular system and fusion of tracheal rings—the tracheo-bronchial syrinx.

That muscular development, however, does not necessarily imply great powers of song is, as he rightly remarks, well shown by the fact that the muscles of the raven and thrush are precisely the same in number and distribution. Furthermore, the muscular system of the raven is the better developed of the two; but there can be no doubt, in spite of this, which is the better songster! Again, though the songs of the true Passeres are extremely varied, yet there is no perceptible variation in the muscular system; indeed, such variation is obviously unnecessary, for the same bird may, and does, repeat the song of numerous other birds as proficiently as the birds to whom the songs rightly belong.

It is interesting to note that Dr. Häcker seems to have shown that sexual distinctions in the syrinx can undoubtedly be demonstrated, that of the female being always more feebly developed. This being the case, one would scarcely have supposed that the female, as in the case of the bullfinch, for instance, would sing as well as the male, but so it is.

Castration acts directly on the syrinx, much as on the horns of deer, for instance; the capon having a syrinx like that of the female. Young males appear to have a more powerful syrinx than adult females.

The chapter dealing with the development of song and other forms of display are full of thoughtful matter. Special mention is given to Rohweder's recent interpretation of the curious bleating or drumming of the snipe. This observer contends that this strange music is caused by the rapid vibration of the horizontally extended and half-closed wings, which drive a strong current of air against the stiffened outer tail feathers, setting them in rapid vibration, and causing the curious tremulous bleating sound. This explanation differs somewhat from that of Meeves and others, and is probably the most nearly correct explanation we have yet had.

We heartily commend the book to the notice of ornithologists. W. P. P.

Physikalisch-chemische Propädeutik. Zweite Hälfte, 1–3 Lieferungen. Von H. Griesbach. (Leipzig: W. Engelmann, 1896–1900.)

THIS book, the first part of which has already been reviewed in NATURE, is chiefly intended for those interested in medical science. In it Prof. Griesbach discourses of everything from the law of gravitation and the conception of potential to the chemical nature of disinfectants and the morphology and physiology of bacteria. There is no particular arrangement in the book; chapter xxiii, on molecular mixtures, occupies 232 pages, whilst chapter xxiv, on the factors of energy, occupies 4. It must not be supposed, however, that the book is on this account uninteresting—far from it; it is excellent reading, and is both wonderfully accurate and wonderfully complete. Indeed, the struggle after completeness seems to be the author's chief failing. In connection with semipermeable membranes, he happens to mention sugar. This at once prompts him to give the means of detecting sugar:—smell of caramel, "French word from Latin *canna mellis*, honey-cane, *i.e.* sugar cane," and reduction of Fehling's solution, which necessitates a short biography of Fehling. Exact instructions for the preparation and use of Fehling's solution are then given. This, of course, involves reference to Rochelle salt, whence "Pierre Seignette, born when and where? physician and apothecary in Rochelle, died at Rochelle, 11 March, 1719." After nearly two large and closely printed pages we get back once more to semipermeable membranes. This is propædeutic with a vengeance.

Despite its faults of method the book is a mine of valuable information, and can be cordially recommended to any medical man with a taste for the physical sciences.

Annals of Politics and Culture (1492–1899). By G. P. Gooch, M.A., with an introductory note by Lord Acton. Pp. 530. (Cambridge: University Press, 1901). Price 7*s*. 6*d*. net.

THE object of this work, as set forth in the preface, may at first sight appear pretentious and impossible of achievement, viz., to present "a concise summary of modern times, embracing the life of mankind in its entire range of thought and action." As soon, however, as the reader has mastered the plan of the book it will be found that the author has carried out his object—originally suggested by Lord Acton—with remarkable skill and completeness. Politics occupy the left and culture the right hand series of pages. At the top corner of each page is the date in conspicuous type, and a further subdivision under the two headings enables the reader to pick out at once the particular subject or country. The political subjects are classified under countries and the culture subjects under various headings, such as art, science, philology, history, philosophy, literature, education, economics, archæology, social, deaths, &c. Of course it is the scientific references that will chiefly appeal to our readers, and so far as we have tested these they appear to be both accurate and complete. The author has evidently been well advised in his choice of scientific events and due proportion as to the relative importance of discoveries in different branches of science which, under a chronological classification, have necessarily to be brought into juxtaposition, has on the whole been carefully observed throughout the long period of more than four centuries covered by the work. A very complete index, composed both of names and subjects, is correlated with the contents of the volume by reference numbers and not pages, ordinary numerals referring to politics and italicised numerals to culture subjects. As a book of reference, workers in the history of science will find Mr. Gooch's volume of great value. R. M.

The Child: His Nature and Nurture. By W. B. Drummond. Pp. 146. (London: J. M. Dent and Co.; no date.) Price, 1*s*. net.

IN the preface of this primer it is stated that the book is intended as an introduction to the study of the physical and mental development of the child, and it is admirably fitted for this purpose. It covers a wide range, but is concise, clear and interesting, and brings within a small compass the result of recent work in the study of children. It is a book which should be in the hands of every one who has to do with children, and besides being a practical help in dealing with the infant and growing child, we think it will stimulate further child-study.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Smithsonian Solar Eclipse Expedition.

THE Smithsonian Institution has sent out a small party to Sumatra, under the immediate charge of Mr. C. G. Abbot, to continue certain of the observations described in NATURE of July 12, 1900, where these, on account of the narrowness of the eclipse track and the brevity of the time, were indeterminate.

The expedition sailed on February 16 in the Government transport *Sheridan*, and the Institution has learned of the arrival of the party at Padang, Sumatra, on the *General Alava*, a United States naval vessel.

The objects principally sought are, such a thorough photographic search in the neighbourhood of the sun, for possible intramercurial planets, as may be apt to set the question of their existence at rest; and also a further and more complete study, by the bolometer, of the heat of the corona.

The observations of May 1900 were three in number:—

(1) One on the radiation from the screen. This was arbitrary and may be called zero.

(2) One on the dark moon, giving on the millimetre scale -18, showing that the bolometer was radiating to the moon.

(3) One on the inner corona, giving -13, showing that the bolometer was radiating to it, though in a less degree than to the moon.

The algebraically increased reading for the coronal radiation then $(-13-(-18) = +5)$ was probably due to this coronal radiation, together with possibly something from the different radiations of the closely neighbouring parts of the sky used in the two observations.

Since the Wadesboro experiments the bolometer has been set on a screen of its own temperature, giving zero; on the bright moon, giving $+55$, and on the night sky near the moon, giving -30.

From my study of the visual photometric observations made at Pike's Peak in 1878, and at other places, it appears that the average visual brightness of the portion of the corona covering the bolometer at Wadesboro was approximately equal to that of the full moon.

I infer, then, that the full moon being of the average brightness of the observed portion of the inner corona, the bolometric effect of its visual radiation may be supposed to be equal to that of the latter; but the observations above recorded show that the total radiations from the moon being $55+30$, or eighty-five bolometric divisions, are seventeen times as great as the radiations from the inner corona, and hence it may be supposed that the corona lacks that large amount of infra-red radiation which is proper to the moon's spectrum.

The moon's spectrum, however, is that of a heated solid body, and all heated solid bodies, and heated gaseous bodies as well, send to the bolometer large amounts of infra-red radiation. So far, then, we might conclude that the inner corona has not the radiations of a hot solid or gaseous body, but, owing to the lack of a contemporary measure of the sky radiation just outside the corona, and of a full knowledge of the influences that the atmospheric radiations would have on our ability to discriminate this, the above conclusions seemed to me only probable, and worth verification at the forthcoming eclipse.

Smithsonian Institution, April 29. S. P. LANGLEY.

The Persistence of the Spectrum of Carbon Monoxide.

THE letter of Dr. Carl v. Wesendonk (p. 29), which gives an account of the spectrum of carbon monoxide appearing in a vacuum tube containing silicon tetrafluoride, affords an instance of the extreme difficulty of obtaining vacuum tubes charged with perfectly pure substances. The case he cites of silicon fluoride being prepared from "pure" sulphuric acid, glass and fluor spar, without any but glass joints to connect the different parts of the apparatus, is one in which neither the perfect freedom of the sulphuric acid, nor of the glass itself, from carbon compounds can be relied upon. In experiments on the absorption spectrum of ozone made by me in 1881, it was found that strong sulphuric acid free from all the usual impurities was not absolutely clear, but by being kept in an atmosphere containing a large proportion of ozone it became perfectly brilliant and absolutely colourless when seen in volumes of half a gallon to two gallons at a time. It appeared from further experiments that the impurities were either carbon or some form of organic matter probably coming from dust or dirt. As to the purity of the glass used for vacuum tubes, it may be remarked that dust and condensed vapour from carbonaceous matter, such as the products of combustion from lamp oil or coal, adheres to its surface with much tenacity. It is probable that the fluor spar contained organic matter, for the reason that this substance is associated with limestone of a bituminous character in England and that it has been asserted that its colour is due to organic substances. By the action of sulphuric acid a gaseous carbon compound might easily be evolved which would contaminate the silicon fluoride even if there were no carbonates present. Next we have to consider the traces of air which may remain in the tube, and must not regard these as being absolutely free from hydrocarbons. M. Armand Gautier has shown that there are combustible gases in the atmosphere, one of which is a hydrocarbon, the other hydrogen, and there is also some carbon monoxide. The difficulty of removing these by ordinary chemical treatment is so great that special operations and reagents were provided for their removal.

In vacuum tubes it is known that carbon monoxide shows its spectrum brilliantly when the pressure is extremely low, and that subsequently it disappears. The very interesting research of Prof. Smithells on "The Spectra of Carbon Compounds," in the April number of the *Phil. Mag.*, illustrates this. Furthermore, it shows distinctly that the same spectrum is obtainable from both carbon monoxide and carbon dioxide (*loc. cit.* pp. 489 and 490). We know, too, from the experiments of Regnault and of Bunsen on the analysis of atmospheric air, that carbon dioxide is absorbed by glass. In view of the facts quoted by Prof. Smithells, the carbon monoxide spectrum is, in his opinion, really due to carbon dioxide, but this latter may easily be decomposed into carbon monoxide and oxygen under the influence of the spark discharge.

The Swan spectrum, attributed variously to a hydrocarbon and to the element carbon by previous investigators, is, according to Smithells, to be attributed to carbon monoxide. It appears also in Dr. v. Wesendonk's letter that when the glass tubes in which the electrodes were fused had become heated, the carbon monoxide spectrum was faintly visible. This would be quite in accordance with the probability that carbon dioxide was evolved from the glass.

A tube containing silicon hydride also showed the carbon monoxide and the Swan spectrum, as well as hydrogen and mercury lines, but no silicon lines were observable. Considering all the facts of the case, it is not conceivable that the spectra in question arise in any way from the decomposition or dissociation of the silicon in the compound, either in the state of vapour as fluoride, of gas as hydride, or in the solid state as glass. W. N. HARTLEY.

April 25.

The Use of "Axis-vectors."

THE effort to popularise the elements of vector algebra is commendable. The power and the direct insight conferred by the use of vector quantities should be sought consistently in the study of physics; and it is true that the introduction of these methods has been needlessly postponed. But it lies in the very nature of such benefits that they are not to be secured except upon tenable grounds and as the result of a continuous argument. If a particular quantity is to be classed with vectors, that cannot be done upon a basis which is reducible to the bare statement: "This magnitude may be represented by a straight line of given direction and length; therefore it is a vector." Witness, for example, moment of inertia, which is not properly a vector, although its magnitude can be associated with a rotation-axis. Vector quantities must be subject to the process of "geometrical addition"; there is a total obtainable as the vector sum of constituent parts. This is equivalent to saying that there is a greatest value Q (resultant) for one direction, and that the law of orthogonal projection applies. Thus the value Q_1 for any other direction must satisfy the equation

$$Q_1 = Q \cos (Q_1, Q).$$

This projective property must be proved somehow in each case.

The conception of a vector is usually established as an elementary matter with the aid of instances like velocity and force. Velocity is so closely connected with linear displacement that the operations of geometrical addition and projection can be almost intuitively recognised as valid for both quantities. The graphical representation of forces, and the application to them of the "parallelogram construction," can be approached from the experimental side, furnishing a timely reminder that this procedure (as regards physical quantity) is ultimately justified by appeal to phenomena. The inclusion of "axis-vectors" (*e.g.* angular velocity and acceleration; moments of force and of momentum) in the class is a second step, of no less importance than the first. The proofs put forward to cover this extension of the thought afford fruitful material to the student of applied logic, through their variations of scope and emphasis. The analysis of some demonstrations now current prompts the remarks which follow.

First, linear vectors, like velocity, force, magnetic field, have what may be termed objective direction. But direction is assignable to axis-vectors by usage only, in the line of a (possible or actual) rotation-axis. Further, the sense in this line is arbitrary, being determined, for example, by the "rule of the right-handed screw." This double convention underlying the graphical representation of axis-vectors must be insisted upon.

Secondly, the theorem known as the "parallelogram of angular velocities" is really intended to prove that the linear velocities of all points in a rigid body satisfy the conditions of rotation in certain cases. The characteristic of rotation is a relation to the axis as regards the direction and the magnitude of all velocities, usually expressed as $v=r\omega$, v being perpendicular to both r and the rotation-axis. The proof of the theorem is only implicitly complete, if we content ourselves with showing that simultaneous angular velocities about intersecting axes produce zero linear velocity on a particular line. And the corollary covering the most important point is often not even mentioned. Similar considerations apply to angular acceleration.

Thirdly, the direct graphical representation of force-moment is connected with areas and not with lines. These areas are in general parallelograms, with adjacent sides representing the force and the distance of its point of application from a chosen point on the rotation-axis. The fundamental case is that in which the parallelogram is perpendicular to the axis, and its area shows the moment for a line through one vertex. For an oblique axis through the same vertex, the moment is obtained by projecting that area upon a plane perpendicular to the new axis. This follows easily from the definition of force-moment.

On adopting a convention governing signs, couple-moment can be represented, for a normal axis, by an algebraic sum of areas. The application here also of the projection-process is an immediate consequence, and it is seen that the values of couple-moment for all parallel axes are equal. The final step in making the transition to the axis-vector is the convention according to which areas are represented by lengths properly laid off on their normals. The process of reasoning for moment of momentum is entirely parallel to that outlined for moment of force. And it can be shown (cf. Heaviside, "Electromagnetic Theory," i. p. 181) to cover the cases of angular velocity and acceleration. For the representation of an area by a length of its normal is the basis of the idea in the vector product of two vectors. The argument of the present instance forms a good elementary introduction to that conception. F. SLATE.

University of California, April 24.

The New Comet.

ALTHOUGH others besides myself have probably noticed the remarkable inconsistencies in the published reports of the new comet, it seems worth while to draw attention to them. Its reported position for April 25, May 2 and May 4 are based on telegrams from the Cape and Peru, and there seems no reason to doubt their correctness. If, however, they are accurate, the comet could not have been seen in England in the morning, as at no time did it rise till after the sun. Yet Mr. Chambers saw it at Eastbourne at 3.5 a.m. on the 2nd, and a correspondent in the *Daily News* says it was fifteen degrees above the southern horizon at 3.30 a.m. on the 7th. E. C. WILLIS.

Southwell Lodge, Ipswich Road, Norwich, May 13.

Blood-Rain.

IN view of the recent letters in NATURE regarding the fall of red rain in Italy, the following extract from Roger of Wendover's Chronicles of the year 1223 may possibly be of interest:—"In the same year it rained blood-coloured earth at Rome for three days, to the great wonder of numbers of people (vol ii. p. 444 of Bohn's edition of Wendover's "Flowers of History.") It is rather curious that so miserably superstitious a *gobemouche* as Wendover should have described the phenomenon so accurately instead of calling it a rain of blood.

Polperro, Cornwall. F. H. PERRY-COSTE.

THE ANTI-VIVISECTION SOCIETY AND LORD LISTER.

THE Anti-Vivisection Society held its annual meeting last week in St. James's Hall. We know these annual meetings; they are accompanied by an annual crop of distortions of scientific work and an annual volley of scurrilous charges against scientific workers and philanthropic administrators. Beforehand, all the perseverance of the accomplished party "whip" is drawn upon to get these meetings together, and afterwards all the ingenuity of the unscrupulous pamphleteer to boom in the Press what has taken place at them. The usual copies of certain daily papers marked in blue pencil under the name of Mr. Stephen Coleridge are sent out broadcast, reporting in detail the sentiments of the audience and the horrors of so-called vivisectors. Were this all it might well be passed over in contemptuous silence, but this year it pleased the meeting to impugn the philanthropic impartiality of one whom all the scientific, and indeed cultured, world delights to honour.

Mr. Coleridge gravely informed his audience, after having discoursed inaccurately on Lord Lister's scientific work, that this man of science was the intimate friend of fifty-eight licensed vivisectors, presumably because he had signed a certificate exempting them from the use of anæsthetics in their scientific experiments. These certificates were signed by Lord Lister in his capacity as president of the Royal Society, and the probability is that personally he was not acquainted with half-a-dozen of the licensees. Mr. Coleridge carefully avoided telling his audience that the vast majority of these "horrid vivisections," in which the use of anæsthetics was dispensed with, were simply inoculations, or, in other words, mere pin-pricks; also that by the Prevention of Cruelty to Animals Act only very few persons of high scientific standing and training can sign these certificates, and that the president of the Royal Society is one.

Mr. Coleridge next turned his attention to scurrilous charges against Lord Lister, in particular, as chairman, and the committee, in general, of the Prince of Wales's Hospital Fund. He impugned the integrity of these gentlemen in that he stated they had given larger grants per bed to those hospitals which either had licensed laboratories attached to their medical schools, or had upon their staffs physicians and surgeons who were actually vivisecting, or had at some past time done so, than to those hospitals which had no connection either direct or remote with vivisectors. Further, that the Hospital Fund Committee had done this with the express object of encouraging so-called vivisection. Mr. Coleridge deduced the necessary corollary from this assertion, and stated point-blank that the Prince of Wales's Hospital Fund had simply been used to endow vivisection on a huge scale.

If we examine the facts we shall find that any hospital in London of any eminence whatever and performing philanthropic work of any magnitude, has upon its staff physicians and surgeons who have at one time or another experimented on animals. The small hospitals received small grants because their need was relatively small, and the large hospitals large grants because their need was relatively large, not because the former were unconnected and the latter connected with so-called vivisectors. Mr. Coleridge did not include in his speech the fact that he himself had endeavoured to strike a bargain with a London hospital, promising this institution the pecuniary support of the Anti-Vivisection Society if it would exclude from its staff all those whose medical knowledge had been derived from experiments upon living animals. The reply of this institution is worthy of record: it refused to allow any other considerations than those of medical or surgical efficiency to guide it in the choice of its officers.

This point has just now a very special interest, in that we believe that vivisection is to be made a party cry in the case of contributions to the Hospital Sunday Fund. Contributors are to be asked by the Anti-Vivisection Society when giving their contributions to demand that they shall only be devoted to hospitals having no connection with vivisectors or vivisection. So valuable have the results of experiments upon animals been to medical science that scarcely a hospital can be found independent of medical men who have derived their knowledge from them; and the Anti-Vivisection Society, with all its ingenuity and perseverance, cannot find amongst the ranks of its supporters a single medical man or indeed biologist of eminence. It is earnestly to be hoped that this fact will have its full weight with all contributors to hospitals, and that they will give their donations as they have done before, resting assured that their money will be duly apportioned by competent philanthropists accustomed to weighing justly the relative claims of charitable institutions, and not easily influenced by the clamourings, however loud, of ignorant partisans.

THE ARMY EDUCATION COMMITTEE.

WE are glad to learn that Sir Michael Foster has been added to the committee appointed to consider the present methods of selecting and training officers for the various branches of the Army. As stated in our number of May 2 (p. 23), this committee, as originally constituted, consisted of Colonel Jelf, Lieut.-Colonel Hammersley and Captain Lee, together with the Head Master of Eton, the High Master of St. Paul's, and the Right Hon. A. Akers-Douglas (chairman) and Captain Cairnes (secretary). Such a change as that which has been made was therefore very desirable, and we feel sure that the addition of a representative of science to the committee will meet with general approval.

As the methods of selecting candidates for the Army have been altered repeatedly during the last twenty years, and as the present regulations, which we owe largely to the exertions of Sir Henry Roscoe, came into action no later than November 1898, it is clear that only an exceedingly small proportion of our present officers have been selected under those regulations and that only a few of these can as yet have reached positions higher than that of a lieutenant. It is certain, therefore, that any defects that may have been detected during the trials of the last two years must, so far as they are due to systems of selection at all, be the outcome, not of the present system, but of those narrower schemes which preceded it, and which, as we pointed out again and again before they were altered, tended to exclude certain classes of candidates from a profession which they were well fitted to adorn. This defect was remedied by the regulations now in force, and we trust that whatever changes may be found necessary there will be no reverting at this critical moment to the narrower policies of the earlier scheme.

There is said to be a strong and, we would venture to add, a highly reasonable feeling on the part of leading military authorities that what the Army wants is a plentiful supply of able candidates. If this be true, as we hope it is, we trust that the committee may find themselves able to make recommendations which will enable clever candidates who may not happen to be endowed with private incomes, or to be cadets of well-to-do families, to enter the Army more freely in the future than has been possible in the past. And, secondly, that they will take care that any new scheme of examination they may propose shall have no tendency to restrict the field of selection, but offer reasonably equal chances, as the present scheme does, to candidates of all suitable types and aptitudes. It would be a national misfortune if any present necessity of the Army should be made the basis of changes which would tend to reproduce the conditions of ten or a dozen years ago.

STUDIES ON THE STRUCTURE OF THE UNIVERSE.[1]

A VERY interesting publication has recently been issued by Mr. Stratonoff, of the Russian Observatory at Tachkent, on the structure of the universe, a problem which has a fascination of its own for most readers quite apart from any real progress which may be made towards its solution.

The question is so vast that the researches of our greatest astronomers have done little more than lead us to the top of Pisgar and show us from afar the promised land, but every newly ascertained fact, or even confirmation of old ones, is a valuable contribution towards the general stock of knowledge which is being gradually accumulated, out of which, perhaps, the genius of some future Newton may evolve some general law.

Before any real advance can be made in the study of the structure of the universe, it is necessary to commence, and perhaps finish, with the Milky Way, that great band of faint stars which has puzzled mankind from the earliest times and which has been explained more according to the imagination of the observers than with any regard to the facts. Indeed, before the age of modern scientific instruments there were no facts to explain anything, and even now, with all our present resources, fresh facts are only being very slowly brought out; we still depend very largely on eye observations, only the eye we now use is the photographic camera.

We know in a general way that the galaxy is composed of very faint stars, presumably at an immense distance from our system, and that the stars have a tendency to thin out as we leave this region and approach the galactic poles. The great researches of Herschel, W. Struve, Argelander and Seeliger have thrown much light on the distribution of the larger stars as shown in the various catalogues; there, however, still remained the telescopic stars to deal with, and it is this part of the question that Mr. Stratonoff has taken in hand.

Mr. Stratonoff has devoted himself to the making of a series of charts showing the distribution of the stars in the northern hemisphere and down to 20° south, and for this purpose he has divided the part of the sky dealt with into 1800 separate areas, and tables are given showing the density of the stars in each. These particulars are represented in the maps by a colour scale by which the regions containing the largest number of stars may be seen at a glance.

The first eight maps show the distribution of stars to each half magnitude from the 6th to 9·5; and the well-known tendency of the stars below the 6th magnitude to leave the poles and crowd more and more towards the galactic equator is well shown in the case of each magnitude.

The Milky Way itself Mr. Stratonoff considers to be an agglomeration of immense condensations, or stellar clouds, which are scattered round the region of the galactic equator. These clouds, or masses of stars, sometimes leave spaces between them and sometimes they overlap, and in this way he accounts for the great rifts, like the Coal Sack, which allow us to see through this great circle of light.

Mr. Stratonoff also finds evidence of other condensations of stars in these maps; the nearest is one of which our sun is a member, chiefly composed of stars of the higher magnitudes, which thin out rapidly as the Milky Way is approached.

A second condensation is also found at a distance represented by the stars of magnitudes from 6·5 to 8·5, and a third, still further off, at about the distance occupied by stars of magnitudes from 7·6 to 8.

Mr. Stratonoff has also pushed his inquiries into the distribution of the stars according to their spectral type.

For the purposes of this inquiry the Draper Catalogue has provided the materials. In this catalogue the stars are divided into sixteen classes, known by letters from A to Q. In order, however, to facilitate mapping, Mr. Stratonoff has put all these classes into two:—Class I. embraces the divisions A, B, C and D, and Class II. takes in the rest. These two classes are too large to make these two maps of the distribution of the spectral types of much service, but they may be taken to give some rough idea of the position in the heavens of the stars of Secchi's types I. and II. From a glance at these maps it is seen that the stars of type I., which includes the Sirian and Orion stars, are situated principally near the Milky Way, while those of type II., which includes our sun, are principally condensed in a region coinciding roughly with the terrestrial pole, and only show a slight increase, as compared with other stars, as the galaxy is approached.

This mapping out of stars in their spectral classes is of the highest interest in the study of the structure of the universe, but we doubt whether the study of these types is sufficiently advanced to get any real information which can assist the student in this respect, and we must be content to wait until a far larger number of stars has been accurately observed before such maps can have anything more than a passing value. Mr. Stratonoff, however, has skilfully used the material he had, and we hope that he will take up this part of his subject later on.

[1] "Publications de l'Observatoire Astronomique et Physique de Tachkent. Etudes sur la Structure de l'Univers," par W. Stratonoff, Astrophysician de l Observatoire de Tachkent.

The atlas also contains five maps showing the distribution of the nebulæ in the northern and southern hemispheres according to the various classes into which they are generally divided. Mr. Stratonoff states that the law which operates to cause the galaxy to be poor in nebulæ is a general one and extends to all classes of these objects, bright, feeble, large and extended. The nebulæ, however, do not appear to have been studied from a spectroscopic point of view, as it is well known that the gaseous nebulæ are chiefly found in the Milky Way.

The last map is devoted to star clusters in both hemispheres, and shows that these objects are intimately connected with the galaxy, the globular clusters, as distinct from star clusters generally, being the only ones which show no tendency to accumulate in this region.

Mr. Stratonoff has executed a laborious piece of research, and we congratulate him on making so interesting a contribution to stellar literature. HOWARD PAYN.

THE GEOLOGICAL SOCIETY AND ITS MUSEUM.[1]

THE Geological Society of London, which was founded in 1807, began in early days to accumulate a collection of rocks and fossils, minerals and recent shells; and when, in 1828, the Society was provided with apartments in Somerset House, adequate space was afforded for the arrangement of the museum. Although many specimens were distributed throughout the rooms, two of these were specially set aside for the museum, an upper room containing the foreign specimens and a lower room mainly for the British rocks and fossils, while the minerals and recent shells were stored in cabinets in the smaller library. The museum then supplied a real educational want, and was of great service in preserving specimens which illustrated many of the papers read before the Society and published in its *Transactions*. Its state may be judged of from the Report of the committee in 1836; they express "the pleasure they derived from the excellent state of preservation of the whole museum, and from the unwearied zeal and discriminating skill displayed by the curator in arranging the collections." For fourteen years William Lonsdale devoted himself to the welfare of the Society, not only reorganising the museum but editing the publications. He retired in 1842 and was succeeded by Edward Forbes. There is no doubt that in those days the museum was fully appreciated, and the lower room particularly, with its cosy fires, was in winter time a pleasant resort for conversation and study.

Meanwhile, however, the work of the Society increased, the library growing especially, while the museum made little progress, and although a curator (who gave his whole time to the museum) was now and again appointed for a period, it was not possible to offer remuneration sufficient for the purpose; and increasing difficulty was felt in keeping the collections properly named and in proper order. In 1868 the Council "decided on the discontinuance of the formation of a general collection," and restricted it "in future to specimens illustrative of papers read before the Society and those received from abroad." In 1874 the Society removed to its present rooms in Burlington House, and took the opportunity to present "superfluous duplicates" to the British Museum, the Museum of Practical Geology and other institutions. Since this date, however, the museum, while occupying valuable space, has been of comparatively little service to science or to any of the fellows. The collection, as a whole, has been sadly neglected, owing to the fact that the other work of the Society has fully occupied the officers. It has been realised, too, that the want which the Society in its earlier days supplied was now better supplied elsewhere, and that the fellows have ceased to take much personal interest in the museum. As Sir John Evans remarked, in his address to the Society in 1875, "the best home for a collection of British specimens was at the headquarters of the Geological Survey" in the Museum of Practical Geology. In 1896 a proposal was made to transfer great part of the Geological Society's collection to the British Museum, but the transfer was not then agreed to. On March 27 of the present year a special general meeting of the Society was again called to consider the matter, and it was then resolved "That in the opinion of this meeting the time has now come when this Society shall transfer its collections to some other museum." That this is a wise resolution most of those who know the museum and value its contents will cordially agree. Nor is this view inconsistent with the possession of a considerable amount of sentiment for the museum and its associations with the early history of the Society, with Greenough, Lonsdale, Fitton, Murchison, Leonard Horner, Daniel Sharpe, Falconer and others who actually worked in the museum or largely contributed to its stores. Those inspired with such sentiment would prefer to see the specimens well taken care of and accessible. It is reckoned that there are 2460 figured or described fossils. In the interests of geological science it is desirable that these be placed in the British Museum, Cromwell Road, where as many type-specimens as possible should be deposited; and it would not be difficult to find appropriate resting-places for all other specimens worthy of preservation.

The question is simply this: How can the specimens in the museum be best dealt with in the interests of geological science? And we hope the Society will soon settle it to the satisfaction of the fellows and of geologists in general.

[1] An article on "The New Museum of the Geological Society" at Burlington House, appeared in NATURE for January 20, 1876, p. 227.

THE ROYAL SOCIETY CONVERSAZIONE.

THE conversazione held at the rooms of the Royal Society on May 8 was a very successful one, and a large gathering assembled to examine the many interesting objects contributed by the fellows and others. We regret that the pressure on our space does not permit the publication of the various explanations carefully given in the official catalogue. But some of the more important of the exhibits have already been referred to in our columns, and we propose to return to more of them later on.

Mr. J. E. S. Moore, the Tanganyika problem. This exhibit was intended to give some idea of the additions which have been made by Mr. Moore, during the second Tanganyika Expedition, to our knowledge of the faunæ in the great African lakes.

Dr. H. E. Annett and Mr. J. E. Dutton, of the School of Tropical Medicine, University College, Liverpool: (1) Specimens of some new blood Filariæ, (2) specimens illustrating the life-history of *Ankylostoma duodenale* of the Chimpanzee. Mr. J. Mackenzie Davidson: (1) Stereoscopic transparencies of electrical discharges, and (2) skiagrams of bullet wounds. Mr. Eric S. Bruce, the meteo-parachute, a new instrument for investigating the upper atmosphere.

Commander D. Wilson-Barker, cloud photographs. Prof. J. W. Judd, F.R.S., on behalf of the Coral Reef Committee of the Royal Society, specimens of Foraminifera and Ostracoda, from Funafuti, Ellice Islands. Mr. H. J. Elwes, F.R.S., reversible drawers of butterflies from the Holarctic Region arranged to show wide distribution and adaptability to extremes of climate. Also to show variation and difficulty of applying binomial system of nomenclature. Mr. Killingworth Hedges, fulgurites, or lightning tubes, from the sand hills at Kensington, N.S.W.

Mr. J. E. Barnard and Dr. Allan Macfadyen exhibited luminous bacteria (from the Bacteriological Laboratory of the Jenner Institute of Preventive Medicine). The luminous bacteria are a group of organisms, whose natural habitat is sea-water. They are the cause of the so-called phosphorescence to be seen at times on such objects as dead fish, meat, or other substances which are suitable soils for their growth and development. Their luminous properties are dependent on a supply of free oxygen and a suitable percentage of a soluble chloride in the nutritive medium. The exhibit consisted of artificial cultivations of these organisms on suitable nutrient soils, and showed their luminous properties and the variations that occur under different physical conditions.

Mr. Everard im Thurn, C.B., C.M.G., exhibited arrow-heads of rock crystal from British Guiana, and orchids growing wild in British Guiana; Mr. Vaughan Cornish, photographs of waves, &c., in sand, cloud and snow; Mr. J. Wimshurst, F.R.S., photographs which exhibit some of the properties of the light emitted by Röntgen ray tubes; Mr. Hugh Ramage, diagrams of corresponding lines in homologous spectra; the Meteorological Office, pilot charts of the North Atlantic and Mediterranean for April and May, 1901; the Cambridge Scientific Instrument Company, Ltd., Callendar and Griffith's patent temperature indicator, and photographs of the spectroscope, made for Sir David Gill, for use with the McClean telescope, Royal Observatory, Cape of Good Hope; and the Carl Zeiss Optical Works, stereoscopic binocular range-finder. The reading is taken direct from a scale within the instrument without calculations, giving the distances in meters. Range from 75 to 3000 meters; Prof. J. C. Bose, experiments on binocular alternation of vision; and Mr. R. Shelford, swords and knives from Sarawak, Borneo.

The Director, British Museum (Natural History), exhibited models illustrating the structure of the gills of bivalve mollusca; examples of mormyrid fishes from the Nile; a series of adult and young birds and eggs of the Adelia penguin (*Pygopcelis adeliae*); trephined skulls of natives of the Bismarck Archipelago, collected by the Rev. J. Crump and deposited in the British Museum by Mr. W. E. de Winton. These skulls illustrate native methods of performing the operation of trephining, and are of especial interest owing to the clinical histories of their owners being known. Claw and tooth of Neomylodon Patagonia, and coloured model of the right whale; Prof. A. G. Greenhill, F.R.S., showed a reflecting stereoscope; trochleostatic—diagram and models of pulleys; Mr. C. V. Boys, F.R.S., tool grinding appliance; Dr. Dawson Turner, a mechanical interrupter for an induction coil; and the Marine Biological Association, examples of marine plankton from the neighbourhood of Plymouth. The term marine plankton is used to denote organisms whose normal mode of life is to swim freely in the sea-water, in contradistinction to such as live in contact with the sea-floor. The Observatory, Cambridge, exhibited a machine for measuring astronomical photographs; and Prof. Callendar, F.R.S., a standard barometer.

Photographs of Nova Persei were exhibited by Sir Norman Lockyer, K.C.B., the Rev. W. Sidgreaves, S.J., and Mr. Frank McClean, F.R.S.

The Zoological Society of London exhibited living specimens of the Heloderm (*Heloderma suspectum*) from Arizona, the only venomous lizard known; Dr. J. H. Gladstone, F.R.S., ancient Egyptian gold; Mr. W. Flinders Petrie, casts and photographs of Egyptian jewellery of the 1st dynasty, 4700 B.C., and specimens of molecular transference in ancient bronze; Prof. A. W. Rücker, Sec. R.S., and Prof. J. W. Judd, C.B., F.R.S., specimens of atmospheric dust which fell at Taormina, Sicily, during the month of March, giving rise to the so-called "blood rain"; Sir W. Roberts-Austen, K.C.B., masses of chromium, manganese, ferro-titanium and cobalt. These specimens of metal were reduced from their oxides by means of finely divided aluminium, by Dr. Hans Goldschmidt.

Dr. P. L. Sclater, F.R.S., exhibited two bandoliers from the Semliki Forest, Congo Free State, made from the skin of a new mammal; Dr. H. Woodward, F.R.S., coloured casts of objects of natural history, prepared at the British Museum (Natural History); an enlarged model of the shell of Ascoceras, a cephalopod occurring in the silurian rocks of England, Sweden and North America; and table of British strata, coloured; Mr. G. Abbott exhibited symmetrical concretions, and "growth" in inorganic matter. Also specimens of four varieties of the cellular or magnesian limestone of Sunderland (Permian), which show a striking resemblance to corals, yet are believed to be only concretionary and inorganic. Hon. Walter Rothschild, M.P., exhibited leg bones and egg of *Æpyornis titan*, Madagascar; Mr. W. Duddell exhibited the musical arc. If a *direct current* arc between *solid* carbons be shunted by a suitable self-induction and condenser in series, alternating currents will flow round the shunt circuit, the arc thus converting part of the direct current into alternating current. The frequency of the alternating current is determined, as in the case of the oscillatory discharge of a Leyden jar, by the capacity and the self-induction of the circuit. These alternating currents superposed on the direct current through the arc will cause it to emit musical notes, the pitch of which can be varied by altering the capacity or self-induction, and a tune can be played on the arc by this means.

The Telegraphone Syndicate exhibited the telegraphone. This instrument, the invention of Mr. Poulsen, of Copenhagen, depends for its action upon the fact that the variations of the magnetic field of an electro-magnet are so accurately represented by the magnetisation of a steel wire which is drawn through it, that if the wire be again passed through the field, currents exactly similar to those which produced the magnetisation of the wire are reproduced in the coils of the magnet. This principle has been applied to the reproduction of speech transmitted through an ordinary microphone transmitter.

The following demonstrations were given by means of the electric lantern:—Dr. Arthur Rowe, life-zones in the White Chalk, and their significance in connection with the evolution of species; Mr. Francis Fox, some engineering problems and their solution; Prof. Silvanus P. Thompson, F.R.S., kinematograph diagrams, illustrating magnetic fields.

THE NATIONAL ANTARCTIC EXPEDITION.

PROF. J. W. GREGORY has to-day (May 15) cabled his resignation of the leadership of the scientific staff of the National Antarctic Expedition in circumstances which will shortly be fully explained to the Fellows of the Royal Society by one of their number.

The great majority of scientific men in this country were confident that Prof. Gregory possessed unique qualifications for the post of scientific leader of an expedition in which many branches of science required study and coordination. Under his direction, and with a competent naval head who should have an absolute veto upon all operations which involved risk to ship and crew, great scientific results were assured.

The opposition of the representatives of the Royal Geographical Society, which had obtained most of the funds voluntarily subscribed, and of a few scientific men belonging to the Navy, rendered it impossible that these full powers could be granted; but a compromise acceptable to Prof. Gregory was passed by a large majority (16 to 6) of the Joint Antarctic Committee, including the officers of both societies and almost every expert on their joint lists.

The compromise provided, in the words submitted on February 12 to the joint committee, "that a landing party, if possible, be placed on shore, under the charge of the Director of the Civilian Scientific Staff." Prof. Gregory was informed of this, accepted it, and, the next day, sailed for Melbourne.

The Royal Geographical Society's council refused to accept the compromise, and deputed three of their number to suggest to the officers of the Royal Society that the matter should be settled by a new committee of six, three to be appointed by each council. The Royal Society consented; the committee, chiefly composed of non-experts, met, and proposed modifications which Prof. Gregory has been unable to accept.

We shall await with some interest to see whether the majority of Fellows of the Royal Society, and of other scientific men in this country, will approve the manner in which the Royal Society has acted as the guardian of scientific interests.

NOTES.

INTELLIGENCE has just reached us from Melbourne that on April 10 news had been received from Charlotte Waters, both by letter and telegram, of the safety of Prof. W. Baldwin Spencer and his energetic co-explorer, Mr. Gillen. They report themselves in good health and already busy taking phono- and kinematographic records; and it is good news that the Postmaster-General of South Australia has provided them with a pocket apparatus for tapping the overland telegraph line when in the vicinity of their route. We are also informed that during Prof. Spencer's absence some of his duties are being partly performed by Miss Ada M. Lambert, a distinguished student of the Melbourne University, whose name and work will be well known to all who follow the progress of zoology at the Antipodes.

Dr. Gustav Zeuner, of Dresden, has been elected a correspondant of the Paris Academy of Sciences, in the section of mechanics. Dr. Oudemans has been elected a correspondant in the section of geography and navigation.

One noteworthy feature of the modern educational revival in this country is the gradual conversion and development of the older grammar schools so as to bring them more into harmony with the requirements of the time. Among the latest examples of this enlightened policy is the King's Middle School at Warwick, one of the most ancient foundations in the country. Its founder is said to have been Lady Ethelfleda, daughter of King Alfred, and in date it is coeval with the castle, although the present buildings are modern. The School was opened on May 4 as a School of Science by Sir George Kekewich, who addressed a large meeting in the central hall, in the course of which he said that "science had now come to be regarded as a proper part of the education of every man, in whatever class he might be and in whatever position of life." He added also, among other pregnant remarks, that "it was the new knowledge in science that paid. It was the new knowledge that preserved the nation that produced it in the forefront of commercial and industrial supremacy." The Earl of Warwick, chairman of the board of managers, presided at the meeting, and gave in his opening remarks a brief account of the history of the School and the origin of the present development. The expense of building the new laboratories, &c., has been partly met by a contribution from Sir Thomas White's Charity and partly by a grant from the County Council. Among other speakers who addressed words of encouragement to the managers and scholars were the Countess of Warwick, Dr. Oliver Lodge, representing the nearest University (Birmingham), with which he hoped to see the school hereafter affiliated, Prof. Meldola, Mr. Bolton King, chairman of the Warwickshire Technical Instruction Committee, the Mayor of Warwick, Mr. Alderman Glover and others. The head-master is Mr. H. S. Pyne, who in organising the curriculum hopes to include the scientific subjects bearing upon agriculture, this being the predominant industry in the districts immediately contiguous to the ancient county town. The mining industry is already provided for by a mining school, established elsewhere by the County Council.

The conversazione of the Society of Arts will be held this year at the Royal Botanic Gardens, Regent's Park, on June 28.

Mr. Reginald Smith, of the British Museum, has just conducted a second excavation on the Winklebury Estate, Basingstoke. He found fragments of pottery, which he said undoubtedly belonged to the ancient British period, *i.e.* before the Roman invasion of Britain.

The eighty-fourth annual meeting of the Swiss Natural History Association will be held at Zofingen on August 4–6. At the same time and place, the Swiss Geological, Botanical and Zoological Societies will hold their meetings. Intending visitors should send their names before July 15 to Herr Ulr. Ammann, Zofingen.

The death is announced, on April 8, of Giulio Bizzozero, professor of pathological anatomy of the University of Turin. Bizzozero was born on March 20, 1846, and was elected a fellow of the Accademia dei Lincei on November 12, 1883, and became a senator of the Italian Government in 1890. His best known discoveries refer to the spinous cells of the epidermis, the functions of the medulla of the bones, the intestinal epithelium, and the morphological elements of blood. He founded a school of histology for Italy, and included Golgi among his pupils.

A few days earlier, on April 5, the Accademia dei Lincei was bereft of its president, Signor Angelo Messedaglia, who was born on November 2, 1820, and obtained the fellowship of the Accademia in 1875. Messedaglia's speciality was political economy and statistics, but his knowledge also embraced modern and ancient literature, history, mathematics, astronomy, geography and physics. His last work on Homeric uranology bears abundant testimony to his wide range of study and careful reasoning. He preserved his full activity and intellect nearly till his death.

The steps taken to provide a memorial of Dr. Walter Myers, who lost his life at Para on January 20 from yellow fever, caught while investigating that malady for the Liverpool School of Tropical Medicine, were explained at the last meeting of the committee of the School. The committee has offered to erect memorial brasses in University College, Liverpool, and in Birmingham University, and the offers have been accepted. The School has also erected a tombstone over the grave of Dr. Myers at Para. It has been resolved to found, as a permanency in the School, the Walter Myers Chair of Tropical Medicine, besides a supplementary fellowship for the next five years, to be called the Walter Myers Fellowship of Tropical Medicine.

The Whitsuntide excursion arranged by the Geologists' Association is to the new line of the Great Western Railway from Wooton Bassett to Filton, and the district around Bristol. The party will leave Paddington Station on Saturday, May 25, and return in the following week. Many sections, beds, and other features of geological interest will be examined, and the excursion will be enjoyed by all who take part in it. The Yorkshire Naturalists' Union have arranged an excursion to Brough on Whit-Monday for the investigation of Welton, Elloughton and Brantingham Dales, and the southern extremity of the Yorkshire Wolds.

We are pleased to learn from *Science* that the Legislature of the State of Wisconsin has presented to Dr. S. M. Babcock, of the University of Wisconsin, a fine bronze medal "recognising the great value to the people of this State and the whole world" of his inventions and discoveries, "and his unselfish dedication of these inventions to the public service." Scientific work is so often overlooked by the State that it is pleasing to record the recognition of it. Dr. Babcock's renown rests largely upon his milk test, which has proved of immense value in the dairy industry, but to men of science, who are familiar with dairy and agricultural investigations, his many discoveries in these fields are regarded as even more brilliant and of more value to science than the invention for which he has now been honoured.

The educational and scientific sides of war will receive special attention at the Naval and Military Exhibition shortly to be opened at the Crystal Palace. Demonstrations will be given of wireless telegraphy, the Röntgen rays and other scientific experiments applied to the uses of war in the Army and Navy. The use of the balloon in military operations will be demonstrated; and a special interest attaches to this section, as Sir Redvers Buller is lending the balloon employed by him during the siege of Ladysmith. In connection with this section, and naturally forming part of it, will be an exhibition of war kites, the uses of which will be shown. In an "Arctic" section there will be, not only a large collection of Arctic relics and pictures, but also a tableau illustrating Nansen's polar expedition. In the inventions section a series of the latest and most valuable applications of mechanical science to the needs of the Army and Navy will be on view.

A CHRISTIANIA correspondent of the *Times* reports that the second international Hydrographic Conference held its final meeting on Saturday. The object of the Conference was to complete the international programme of research and the plan of organisation drafted in Stockholm in 1899. The original programme has been revised to meet the wishes of the participating Governments, and it is believed that the new proposals will command such general approval as to permit of the commencement of international investigations at an early date. The Governments of all the countries bordering on the North Sea and the Baltic were represented at the Conference, except France, the geographical position of which gives her less practical interest in the area of research. The Norwegians and Russians have already provided themselves with special steamers adapted to the proposed investigations, and a German steamer is now being built. The arrangements of most of the smaller States are well advanced. It is believed that it now rests with the British Government to decide whether the international programme shall be carried out or not.

THE *Revue Scientifique* contains an account of the first meeting of the "Association Internationale de la Marine," held from April 12 to 15 in the building of the oceanographical museum at Monaco. Amongst the more important communications received was one by H.S.H. the Prince of Monaco on the meteorological service of the Azores, which has recently been actively taken up by the Portuguese Government and is now to be carried on on a very adequate scale at an annual cost of 45,000 francs. M. Charles Bénard, president of the Société d'Océanographie du Golfe de Gascogne, contributed a paper on improvements in the equipment of vessels in case of shipwreck, his proposals embodying, in particular, the suggestions of the Prince of Monaco with regard to proper fishing appliances in ships' boats. M. Thoulet's lithological map of the coasts of the Seine Inferieure was presented, and a resolution urging the need for preparing such maps of all frequented coasts, in the interest both of navigators and fishermen, was adopted. The Congress also declared itself in favour of the establishment of a permanent Bureau Maritime Internationale, which should concern itself with all maritime affairs of international interest, lighting and buoyage, regulation of fisheries, assistance of sailors and the like. The Prince of Monaco, at the earnest invitation of the Congress, agreed to take the initiative in attempting to bring about the formation of the proposed organisation.

THIS year's Deutscher Geographentag will open at Breslau on Monday, May 27. On the morning of May 28 Prof. Neumayer will present the report of a committee upon Antarctic exploration, and will speak upon magnetic investigations in polar regions. Dr. E. Philippi will deal with the geological problems of the German Antarctic expedition, and Prof. A. Supan with the Antarctic climate. At the second sitting the subject to be discussed is the organisation of geographical instruction, the speakers being Prof. H. Wagner, Dr. Auler and Herr H. Fischer. On Wednesday morning, May 29, the subjects to be brought before the meeting relate to the scientific study of lands and native races of German colonies. The speakers will include Prof. F. v. Richthofen, Prof. G. Volkens, Dr. E. Kohlschütter, Prof. K. Dove and Prof. Schenck. The methods of geographical instruction will be discussed in the afternoon of the same day by Dr. A. Becker, Prof. A. Fischer, Prof. A. Kirchhoff, Prof. Langenbeck and Prof. A. Bludau; demonstrations will also be given by Prof. K. Dove and Dr. M. Ebeling. In the evening an illustrated lecture will be given on glacier markings in Montenegro, by Prof. K. Hassert, and one on the volcanoes of central France by Dr. M. Friederichsen. At the fifth sitting, on May 30, the papers will deal with various aspects of glaciers and glaciation, and the speakers will include Profs. Finsterwalder, H. Meyer, S. Günther, A. Penck, W. Goetz and Dr. W. Halbfass. On the afternoon of the same day, reports and papers will be received from Prof. A. Kirchhoff and C. M. Kan, and Dr. K. Sapper; and the general business of the association will be transacted. Excursions have been arranged for a few days at the end of the meeting, and exhibits of geographical interest will be on view in two museums in Breslau. The general secretary, with whom intending visitors should communicate, is Dr. R. Leonhard, Schillerstr. 28, Breslau.

IN the *Journal* of the Quekett Microscopical Club Mr. J. Rheinberg describes a simple contrivance for viewing, under the microscope, the diffraction patterns of diatoms and other objects of similar structure. The method adopted by Dr. Johnstone Stoney is to look at the objective through a small hole fixed near the usual place of the eyepiece. Mr. Rheinberg finds that the diffraction patterns can be better seen above the eyepiece by fixing in a short tube the objective of one of the 7*s.* 6*d.* toy microscopes, which is a lens of about ½-inch focus, stopped down to an aperture of about 1 mm. This arrangement, placed over the ordinary eyepiece, shows the diffraction patterns magnified, and, further, it gives plenty of light, and the patterns cannot shift.

A VERY convenient addition to the laboratory or workshop equipment is the rosin-cored solder recently introduced by the Patent Solder Co., Ltd. This commodity is guaranteed to consist of pure metals mixed in the most efficient ratio, and, as its name implies, has incorporated with it the requisite amount of rosin so that no additional flux is necessary. This is attained by making the solder in the form of a tube with narrow bore, the central cavity being occupied by the flux. The two ingredients being together will facilitate work in difficult positions, and the cleanliness in working will be found a special recommendation for electrical work. The solder is made in four sizes, each of three qualities. The sizes vary from 1/16th to ¼-inch diameter.

THE *Physical Review* for March contains an article by Prof. Carhart on the various determinations of the E.M.F. of the Clark cell. The value originally obtained by Clark reduced to present units at 15° C. is 1·4378 volts, but subsequent research has shown that this is somewhat too high. Prof. Carhart summarises the results of eight other determinations of this constant, in five of which the value was obtained by the use of the silver voltameter, the remaining three values being obtained by absolute methods. The mean value calculated from the whole eight determinations is 1·4335 volts at 15° C., and the mean of the three absolute determinations is 1·4333 volts. Prof. Carhart concludes that the true value is nearer 1·433 volts than the generally accepted value of 1·434 volts. This conclusion is borne out by the results of two determinations of the mechanical equivalent of heat by electrical methods, in both of which the values obtained are higher than those given by direct mechanical methods; if the E.M.F. of the Clark cell is taken as 1·433 volts instead of 1·434, the discrepancies almost disappear.

THE same journal contains an interesting article by Mr. Carl Kinsley on the measurement of the sensitiveness of coherers for wireless telegraphy. Mr. Kinsley urges the desirability of some standard method of comparing coherers so that the work of different experimenters may be compared, and suggests two ways in which this may be done. Coherers may either be compared relatively by measuring the height of vertical wire necessary for them to respond to signals sent by a given transmitting apparatus at a given distance, or, absolutely, by measuring the voltage at which their initial resistance breaks down. The two methods, it is pointed out, always give the same relative results; the latter appears to be preferable as it is more easily carried out, and, moreover, eliminates all errors which might arise through differences in the transmitters, which is especially advantageous in the case in which the work of different persons is being compared. Mr. Kinsley rightly insists that the absolute value of the resistance after the breakdown, whether high or low, is not of much importance, as the relay can always be designed to work well with the particular coherer with which it is intended to use it.

WE have received from the Rev. J. Coronas, S.J., of the Manila Observatory, a discussion of a cyclone (*El baguio del* 8 *de Septiembre*, 1900) which traversed the centre of the island of Luzon and is said to have been the most severe storm experienced during the previous six years. It is satisfactory to note that, notwithstanding the paucity of observations from other stations owing to the disturbed condition of the island, the observatory was able to give notice of the existence of the disturbance in the Pacific three days before its arrival on the coast. The observations are insufficient to determine the track of the storm across the Pacific, but after leaving the west coast of Luzon it took a north-westerly course and, crossing the China Sea, reached the mainland near the north of Hainan on September 11. The fall of the barometer was greatest, and the winds the most violent, in the rear of the cyclone; a considerable rise of the barometer was observed at all stations in the front of the disturbance, and was correctly interpreted as a bad sign. The rise was much more rapid than the subsequent fall. The author discusses at some length the premonitory signs of such disturbances, particularly convergence of cirrus clouds and the swell of the sea; the latter is at times observed some 500 miles in advance of the approaching storm.

IT is reported that an American citizen and a member of the Roman Catholic Church has offered to present to the Pope a telescope larger than that shown at the Paris Exhibition of last year. His Holiness is stated to have accepted the gift, which is now destined to find a prominent place amongst the many valuable instruments of research of the Vatican Observatory, which was presented, just over a century ago, by Cardinal Zelada with the then famous Dollond's telescope. Referring to this gift, the *Lancet* gives some interesting particulars concerning the Vatican Observatory. There seems to be scarcely any doubt that an observatory tower was erected in Rome so far back as some time previous to 1582, and, as it would appear, chiefly in connection with the reform of the Calendar. According to B. Crescenzi, Pope Gregory XIII. was mainly responsible for its erection. It is recorded that the tower was intended exclusively for astronomical observations and researches, and there is, from an historical point of view, every reason to suppose that it was the first celestial watch-tower ever built in Rome. Since its erection, however, and partial endowment by Pope Gregory XIII., it has passed through many and highly complicated vicissitudes. It became of world-wide renown at the beginning of the last century, chiefly on account of the scientific labours and able management of Philip Gili, who, for a period extending over thirty years, was its director. After the death, however, of Gili, which occurred in 1821, it again became quite disorganised. In 1888 the Vatican Observatory commenced a new epoch in its history. In that year the commemoration of the fiftieth anniversary of the priesthood of Pope Leo XIII. took place, and on that occasion all the instruments and apparatus given by members of the Roman Catholic Church interested in celestial and terrestrial physics were brought together, and it then occurred to the organisers of the science section of the Vatican Exposition that they would find a suitable home in the old Gregorian tower. The suggestion was warmly approved and soon carried into effect, and the Observatory has since then taken a place in the first rank.

THE new number of the *Mitteilungen aus den deutschen Schutzgebieten* is, as usual, largely devoted to statistics of meteorological observations and astronomical determinations of positions. A map of East Usambara, on a scale of 1 : 50,000, based on trigonometrical and topographic surveys, accompanies the number, also sketch-maps from surveys of the Kirunga volcano region, and of the Ramu river in New Guinea. There are short articles referring to the maps, and Count Zech contributes an illustrated paper on the production of kola in West Africa.

THE *U.S. Experiment Station Record* states that the agricultural council of the Russian Ministry of Agriculture and Imperial Estates has taken steps in the direction of improving the character of the live stock and the live-stock industry in general of that country. At present this industry is said to be far behind that of other countries, the animals kept being inferior and stock raising receiving comparatively small attention from the farmers. The council has recommended the holding of live-stock shows, with prizes for excellence, the establishment of breeding farms and furnishing of expert assistance in purchasing good breeding animals, the maintenance of local breeding establishments where the service of pure-bred animals can be secured, and loans to municipalities and societies for the purpose of purchasing pure-bred animals and providing for their care. In order to carry out the above measures the Ministry of Agriculture, with the concurrence of the Minister of Finance, has recommended a grant of 5,000,000 roubles (about 500,000*l.*) to begin this work and a quadrennial grant of about 112,500*l.*

THE *Bollettino* of the Italian Geographical Society contains part of a paper by Prof. Gabriele Grasso on the distribution of place-names in the Italian communes, dealing specially with those names which have the word "monte" either as prefix or suffix. Dr. Cosimo de Giorgi contributes an elaborate discussion of the physical geography and geology of the port of Brindisi, and Dr. Giuseppe Stegagno a note on the lakes of the Euganean Hills. With this number is issued the part of the *Bibliografia geografica della regione Italiana*, by L. F. de Magistris, for 1899.

IN his Annual Progress Report of the Geological Survey for the year 1899 (1900) Mr. A. Gibb Maitland points out that the field-work has been carried on in areas occupied by the ancient crystalline rocks, presumably Archæan, where the work has had a direct bearing on economic questions. The Kanowna mining district to the north-east of Coolgardie was reported on by Mr. T. Blatchford. Here the schists, which are much decomposed, are in places highly auriferous, the granitic rocks and the interlacing quartz veins are also auriferous, as well as the alluvial deposits. The parent sources of the gold are the quartz veins and lodes which traverse the crystalline rocks, but there is much gold of secondary origin filling fissures or diffused over cleavage planes. It is remarked that what may be called secondary gold has been deposited from solution, not only in the alluvium and other superficial deposits, but also in the zone of decomposition of the bed rock.

MR. C. S. MINOT has sent us a paper, reprinted from *Science*, in which he describes and illustrates the unit system of laboratory construction. The idea is that the essential requirement of a building intended for laboratory work is a number of rooms of uniform and moderate size, abundantly lighted and conveniently accessible. The size proposed is 23 × 30 feet, and a room of these dimensions will provide working space of 3 feet 6 inches × 5 feet for each of twenty-four students, as well as sufficient space for general use. The only exceptions to the unit-rooms would be the lecture-rooms. It is evident that if an architect has merely to fit rooms of uniform size in a building his designs need only be of a very simple character, and he is, at the same time, given great freedom as to the exterior, which, as Mr. Minot remarks, seems as important to him as the interior is to the users of a building. Many advantages are attached to the unit system of laboratory construction, among them being adaptability and seclusion; and with regard to the construction Mr. Minot states that the cost of a building on the unit plan would be less than for one of equal capacity, but with rooms of the customary irregularity of size.

IN the *Irish Naturalist* for May Dr. R. F. Scharff records from Sligo a woodlouse (*Armadillidium pulchellum*) new to the British fauna. It is typically a northern form, ranging from Scandinavia to Belgium.

NUMBERS 1 and 2 of the fifteenth volume of the *Memorias* of the Society "Antonio Alzate" contain a continuation of the "Alphabetical Cross-reference Catalogue" of the works of the late Prof. Cope. The disadvantage of the mode of quotation adopted is that it is exceedingly difficult to find out which items are the original titles of the papers mentioned. Misprints are also noticeable.

TO the April number of the Johns Hopkins *University Circulars* Dr. C. Grave communicates an important geological and economical study of the oyster-reefs of North Carolina. The author describes the manner in which the oyster-banks of the district in question become, like coral-reefs, gradually converted into islands; and points out that some of the islands in Newport River still display their foundation of oyster-shells, while others exhibit the gradual transformation of an oyster-bank into an island. It is also shown that the history of these reefs affords indications of the proper mode of establishing new oyster-beds for economic purposes. Practical application of these principles has been made, with the result that oyster-culture is now successful in localities where previous attempts to start it had resulted in failure.

IN the *Revue Scientifique* of May 4, M. H. Coupin continues his essay on bird-song, dealing in this section chiefly with birds that imitate sounds other than their own. Very remarkable is the instance of a sparrow imitating the stridulation of the grasshopper. One spring a cage containing a sparrow was hung side by side with another in which were grasshoppers. No notice was taken by the sparrow of his neighbours, but next year, when he was again in the same society, he essayed the grasshoppers' chant. And for the rest of his life, when the grasshoppers had long been dead, the sparrow was accustomed to utter a polyglot song combining the notes of the insect with those of other birds. The fact that young linnets will sometimes learn the song of the nightingale instead of their own is mentioned. And it is also stated that several kinds of birds in Thuringia sing much better than the members of their own species dwelling in the Hartz Mountains.

THE *Zeitschrift* of the Berlin Gesellschaft für Erdkunde devotes the whole of the sixth number of the present volume to a paper on the climatology of Morocco, by Dr. Theobald Fischer. In this paper, which is the completion of the work recently published by the author in an Erganzungsheft of *Petermann's Mitteilungen*, the meagre data available for the region are discussed with great skill and made the foundation of a quite satisfactory outline of its climate. A rainfall map forms an important feature. The seventh number of the same volume contains a short paper, with some good illustrations, on the Rocky Mountains and the Sierra Nevada, by Dr. Emil Deckert, and Dr. S. Passarge contributes a valuable account, with maps, of his geological work in British Bechuanaland.

PROF. W. C. M'INTOSH sends us a copy of his article on the coloration of marine animals which appeared in the *Annals and Magazine of Natural History* for March. While admitting that in certain instances the coloration is for the purpose of protection, the author shows that in many cases it is very difficult to accept such an interpretation as the true reason. In the case of pelagic organisms, for example, where the transparency or faint coloration is assumed to be for protective purposes, he points out "that many of the surface-animals are there only for a limited period during fine weather, and disappear into the depths on the advent of storms and cold." The dog-whelk and the cowry (especially when the soft parts are extruded) are cited as creatures that are fairly conspicuous between tide-marks, and it has yet to be proved that they possess "warning colours." The fact that some cetaceans have their flippers or areas on their bodies white, while others are wholly black, seems to demonstrate that their coloration is not protective, this being supported by the conspicuous nature of a black mass exposed above the surface of the sea. The whole subject, in the author's opinion, demands careful revision.

WE have received vol. xxxii. of the *Proceedings* of the London Mathematical Society, containing papers read at meetings during the first half of last year. The publisher is Mr. Francis Hodgson, Farringdon Street, E.C.

THE Priestley Club, Leeds, has published a list of papers read at its meetings from November 1887 to April 23 of this year. The list shows that many subjects of great scientific importance have been brought before the Club, but we are not able to find whether the papers have been published, and if so, where they can be found.

MESSRS. CASSELL AND CO. have published a new edition (the ninth) of "The North-West Passage by Land," by Viscount Milton and Dr. W. B. Cheadle. The book contains the narrative of an expedition across North America, through the Hudson's Bay Territories, into British Columbia, by one of the northern passes in the Rocky Mountains. It originally appeared in 1865, and gives an interesting description of scenes and adventures in the great country of the Canadian North-West nearly forty years ago.

THE additions to the Zoological Society's Gardens during the past week include two Verreauxi's Guinea-fowl (*Guttera edouardi*) from East Africa, presented by Mr. W. L. Sclater; a Polecat (*Mustela putorius*), British, presented by Mr. F. D. Lea Smith; a Slowworm (*Anguis fragilis*), British, presented by Mr. H. J. M. von Löhr; a Black-handed Spider Monkey (*Ateles geoffroyi*) from Central America, a Kinkajou (*Cercoleptes caudivolvulus*) from South America, a Nylghaie (*Boselaphus tragocamelus*, ♂) from India, a White-browed Amazon (*Chrysotis albifrons*) from Honduras, a Tuberculated Iguana (*Iguana tuberculata*) from Tropical America, twenty-nine Barbadian Anolis (*Anolis alligator*) from the West Indies, four Hybrid Macaws (between *Ara macao* and *A. militaris*), bred in Italy, two Dark Green Snakes (*Zamenis gemonensis*), an Undulated Lizard (*Sceloporus undulatus*), three Brown Newts (*Spelerpes fuscus*), two Spectacled Salamanders (*Salamandrina perspicillata*), European, deposited; two Pintails (*Dafila acuta*), European, purchased; a Japanese Deer (*Cervus sika*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET a (1901).—A circular from the Centralstelle at Kiel furnishes the elements and a short ephemeris of the comet computed by Prof. Kreutz from the Cape observations.

Elements.

$$T = 1901 \text{ April } 24{\cdot}2614 \text{ Berlin M.T.}$$
$$\left.\begin{array}{l} \omega = 202^\circ\ 50'{\cdot}0 \\ \Omega = 109\ \ 57{\cdot}2 \\ i = 131\ \ 26{\cdot}0 \end{array}\right\} 1901{\cdot}0$$
$$\log q = 9{\cdot}38848.$$

Ephemeris for 12h. Berlin Mean Time.

1901.	R.A. h. m. s.	Decl. ° ′	Br.
May 16 ...	5 43 53 ...	+4 7·0 ...	0·07
20 ...	6 4 2 ...	5 20·0 ...	0·04
24 ...	6 20 18 ...	+6 21·2 ...	0·03

The comet is rapidly diminishing in brightness, and is following a north-easterly path through the northern part of Orion.

On the 16th it will be a short distance below Betelgeuse at sunset, and on the 24th near the Eye of Monoceros.

VARIABILITY OF EROS.—A telegram from Prof. E. C. Pickering, through the Centralstelle at Kiel, announces that on May 8 the variation in the light of the minor planet Eros was zero. The determination was made by Prof. O. C. Wendell.

WASHINGTON OBSERVATIONS, 1891–92.—The astronomical, magnetic and meteorological observations made at the United States Naval Observatory at Washington during the years 1891 and 1892 have recently been issued in one volume. After detailed descriptions of the instruments employed, the observations and reductions are given for each of the chief instruments, the transit circle, 26-inch equatorial, and 9·6-inch equatorial. The meteorological observations include those of pressure, temperature, wind, clouds, rain and snow.

An appendix is added containing the second Washington Catalogue of Stars, with the annual results upon which its compilation is based. The star places are all reduced to epoch 1875·0.

STELLAR PHOTOMETRY.—In *Comptes rendus* (vol. cxxxii. pp. 1091–1094) M. B. Baillaud, of the Toulouse Observatory, outlines a method he has recently developed for determining the magnitudes of stars from the measurement of photographs by means of a standard wedge photometer. Of course in this case the images are black on a luminous background, and the law governing the action of the wedge in the ordinary case of extinction of bright points on a dark background is not applicable here. Using a series of determinations on stars of known magnitude for the calibration and determination of constants, M. Baillaud develops the formula necessary for computing magnitudes by the method. On account of the spreading of the images of the brighter stars, producing definite sized discs, the method is less precise than for fainter objects, but it is hoped that much of the uncertainty in these cases may be removed by special expedients, and observations are in progress for fully testing the possibilities of the method.

NEW NEBULÆ.—M. G. Bigourdan gives, in *Comptes rendus* (vol. cxxxii. pp. 1094–1097), a list of fifteen new nebulæ observed by him with the west equatorial at the Paris Observatory (aperture 0·31 metre), during the period 1897–1900.

MUSK-OX AND BISON AT WOBURN ABBEY.

BY the kind favour of the Duchess of Bedford we are enabled to present our readers with a portrait of the young bull musk-ox now living at Woburn Abbey, in its present condition. The specimen is the survivor of a pair of yearling calves from Clavering Island, East Greenland, purchased by the Duke of Bedford in the autumn of 1899. They are believed to have been the first of their kind ever introduced into this country, and although one of the pair survived its arrival only for a very brief period, the other has continued to flourish and there is every hope that it will reach maturity. It is now considerably more than two years old, but although the horns are strongly curved they are still confined to the sides of the head and display no signs of growing on to the forehead, in the middle line of which their expanded bases should almost meet in the fully adult bull. At the time when the photograph was taken the animal was just beginning to shed its winter coat, the hair hanging in fleecy rags on the sides of the face. The great hump of hair on the withers forms a very noticeable feature in the general aspect of the animal.

The white patches on the face of the Woburn musk-ox forms the chief distinctive feature of the Greenland race of the species, which, it will be remembered, was named in this journal for December 13 last *Ovibos moschatus wardi*. It was at that time considered probable that the white-faced form of the musk-ox might be restricted to East Greenland; but specimens brought to the United States by Lieut. Peary from Grinnell Land and Ellesmere Land have enabled Dr. J. A. Allen, in a recent issue of the *Bulletin* of the American Museum of Natural History (vol. xiv. art. 7), to show that it has a much wider range, embracing apparently the whole of such parts of Greenland as are inhabited by these animals, together with the two countries above named. In addition to the difference in colour, Dr. Allen points out that the Greenland musk-ox differs from the typical *Ovibos moschatus* of Arctic America by the form of the horns and fore-hoofs. And he considers that it should be regarded as a species rather than a race; for this he takes the name *Ovibos wardi*, adding that if the Grinnell Land and Ellesmere Land animal should prove distinct it might be named after the intrepid

FIG. 1.—Young male Greenland Musk-ox at Woburn Abbey, photographed by the Duchess of Bedford.

American explorer by whom its skins were sent home. For our own part we see no reason to depart from the view that the Greenland and American musk-oxen are local races of one and the same species.

Another feature of special interest in the magnificent collection of animals at Woburn Abbey is the presence of representatives of both the European and American bison. It is now many years since these two splendid animals were seen side by side in the Zoological Gardens in the Regent's Park, and even then they were not shown in such favourable circumstances as are those at Woburn Abbey, which occupy adjacent paddocks of very large acreage. Of the American bison there is now a small herd, including a magnificent old bull as well as several calves, all of which are in splendid condition. When received, rather more than a year ago, the European bison, of which there were a bull and two cows, were very thin after their long journey from Lithuania; and one of the cows (whose skin is now mounted in the Museum of Science and Art at Edinburgh) did not long survive. The other cow and the bull have, however, greatly improved in condition during the last few months, and it is hoped that they may breed before long. The bull serves to show that, although in regard to its head and shoulders the American bison is the finer animal of the two, yet that its miserably weak hind-quarters render its whole appearance far inferior to that of its European cousin.

R. L.

RESEARCHES ON ORGANIC PEROXIDES.

In the latest number of the *Berichte*, v. Baeyer and Villiger have a number of interesting communications. The preparation of ethyl hydrogen peroxide, $C_2H_5O.OH$ is described. It is obtained by treating diethylsulphate with a solution of hydrogen peroxide in alkaline solution. The liquid is then acidified and distilled, when the new compound passes over between 90° and 100° mixed with alcohol and water. By further treatment a solution may be obtained boiling at 47–49° at 100 mm. and containing 80 per cent. of the peroxide. At the ordinary pressure it boils about 95°. It is soluble in water, alcohol and ether. It has a smell of both bleaching powder and acetaldehyde. A drop on the skin produces inflammation. It is relatively stable and may be kept for many weeks with very slight alteration. By superheating the vapour in a test-tube, a moderate detonation occurs. Dropped on finely divided silver it decomposes with a sharp explosion. It is a weak acid of about the strength of a phenol and gives salts with alkalis and alkaline earths. It is a strong oxidising agent. In studying the action of ethyl hydrogen peroxide with different reagents, the authors find that whereas nitrous acid yields nitric acid with hydrogen peroxide, alkyl nitrites do not give alkyl nitrates, but nitric acid and alcohol. On the other hand, ethyl hydrogen peroxide and nitrous acid or ethyl hydrogen peroxides and alkyl nitrites give in both cases the alkyl nitrate. These reactions are explained on the assumption that an additive compound is first formed from which either water or alcohol is subsequently removed. Moreover, where there is a choice between the removal of an "alkoxyl" or "hydroxyl" group, the latter takes precedence. This alone would not explain the behaviour of ethyl nitrite and hydrogen peroxide, on the one hand, and nitrous acid and ethyl hydrogen peroxide on the other, which should yield the same product, viz., ethyl nitrate.

$$O{:}N.OC_2H_5 + H_2O_2 = O{:}N(OH)_2OC_2H_5 = O_2N.OC_2H_5 + H_2O$$

$$O{:}N.OH + C_2H_5O.OH = O{:}N(OH)_2OC_2H_5 = O_2N.OC_2H_5 + H_2O.$$

But if the peroxides form additive compounds by separation into H and O_2H or $O_2C_2H_5$ ions, the apparently anomalous changes are readily explained.

$$O{:}N.OC_2H_5 + H_2O_2 = O{:}N\begin{array}{l} OC_2H_5 \\ H \\ O.OH \end{array}$$

$$O{:}N.OH + C_2H_5O.OH = O{:}N\begin{array}{l} OH \\ H \\ O.OC_2H_5 \end{array}$$

The nitrosoperoxide acid then by intramolecular rearrangement passes into nitric acid or its ester.

In the same journal, v. Baeyer and Villiger describe a hydrate of sulphurylchoride, $SO_2Cl_2 + 15H_2O$, which they prepare by pouring the acid chloride on ice. The hydrate has the appearance of camphor and remains undecomposed by ice-cold water for hours at a time.

The disputed question as to whether hydrogen peroxide and silver oxide, when brought into contact, yield the oxygen of the metallic oxide as well as an atom of oxygen of the peroxide, which is Thénard's view, or whether, according to Berthelot, the silver oxide acts as a catalysator by reducing the peroxide of hydrogen to water, is determined by v. Baeyer and Villiger in favour of Thénard.

IRON AND STEEL INSTITUTE.

The annual general meeting of the Iron and Steel Institute was held on May 8 and 9. Sir William Roberts-Austen, K.C.B., the retiring president, announced that Andrew Carnegie Research Scholarships, each of the value of 100*l*., had been awarded to Dr. A. Stansfield (London), to Dr. J. A. Mathews (New York) and to Mr. J. Goldberg (Leoben, Austria). Mr. Carnegie announced his intention of doubling his original donation for the purpose of founding these scholarships. Mr. William Whitwell was then inducted into the presidential chair. Having presented the Bessemer Gold Medal for 1901 to Mr. John Edward Stead, in recognition of the value of his investigations of the physical and chemical properties of iron and steel, the president delivered his inaugural address, in which he reviewed the scientific and industrial achievements of the past reign, and enumerated some of the most important problems in metallurgy that still await solution. A vote of thanks to the president for his admirable address was proposed by Mr. Carnegie and seconded by Sir Lowthian Bell.

The first paper read was by Mr. A. Greiner, of Seraing, Belgium, on dust in blast-furnace gases, in which he described the methods adopted to get rid of the dust in blast-furnace gases used as motive power for blowing-engines.

Mr. J. E. Stead then described some clearly defined idiomorphic crystals recently discovered in the hearth of a blast furnace at Blaina, Monmouthshire. They were found in a cavity of the sandstone foundation of a furnace, in which spiegeleisen and ferromanganese had been made. The crystals yielded on analysis: manganese, 51·75; iron, 35·76; silicon, 3·62; carbon, 3·71; oxygen, &c., 5·16. They belong to the orthorhombic system, and the results of measurements by Mr. H. Bauerman and by Mr. L. J. Spencer are given in the paper. The compound is described as a carbo-silicide of manganese and iron.

Mr. J. E. Stead and Mr. John Evans next read an important paper on the influence of copper on steel rails and plates. It is generally thought that copper has a very deleterious effect, and engineers, when buying steel, frequently specify that it must be absent. The authors clearly show, however, that the general opinion is erroneous. They prove that between 0·5 and 1·3 per cent. copper has no deleterious effect on either the hot or cold property of steel; that a very large amount (2 per cent.) makes the steel more liable to be over-heated; and that in small quantities it slightly raises the tenacity and the elastic limit, but, unlike phosphorus, does not sensibly make the steel liable to fracture under sudden shock. Like carbon, it reduces the power of the steel to extend under stress, but this is not pronounced when the quantity is small. The effect is more marked when large quantities are present. Lastly they prove that if the evidence of the open-hearth steel trial can be confirmed, copper, instead of producing redshortness, has the contrary effect of changing redshort steel into steel which will roll without cracking.

Mr. William Garrett, of Cleveland, Ohio, submitted a comparison between American and British rolling-mill practice. The paper was followed by an animated discussion, which was resumed on Thursday.

Mr. R. M. Daelen (Düsseldorf) described some recent developments of the use of hydraulic power in the manufacture of iron and steel.

Mr. Axel Sahlin discussed the economic significance of a high percentage of silicon in pig iron for the acid steel processes. The demand for high silicon in pig iron is, he considers, doing much to hamper progress in a certain branch of the British iron industry.

The paper by Prof. J. O. Arnold on the properties of steel castings embodied research work extending over six years. The lessons taught by the data set forth in the preliminary experiments detailed in this paper show that pure iron and carbon steel is not a suitable material for fulfilling the modern specifications drafted by engineers for steel castings. With iron and carbon castings the ductility demanded can be ensured with ease, but with such ductility it is impossible to correlate the required tenacity. The latter property, it is true, can be obtained from iron and carbon castings, but at the expense of an almost complete loss of ductility. Therefore, as has already been remarked, excepting the nearly pure iron the series of castings described have small manufacturing interests. Nevertheless they form the basis upon which the mechanical influence of silicon and manganese can alone be scientifically measured.

The remaining papers were taken as read. Among these the paper by Mr. Axel Wahlberg, of Stockholm, on Brinell's method of determining hardness and other properties of iron and steel was an elaborate memoir of great importance. The method consists in forcing, by means of pressure, a hardened steel ball into the material to be tested so as to cause an impression, the diameter of which is then to be measured, in order to obtain the spherical area of the concavity. The quotient resulting from dividing the maximum pressure by this area will then represent what is called by Brinell a *hardness number*, indicating, according to him, the amount of pressure (kilograms per square millimetre) to which the material so tested has been subjected. With this method a number of researches have been carried out, detailed particulars of which were given. They relate to the determination of hardness of various metals, to controlling forging tests, and to the hardening of iron and steel. Under the last head experiments were made to ascertain the influence of the percentage of carbon on the hardening capacity, the hardening effect of different quenching liquids, the influence of the temperature of the quenching liquid on the hardening result, the influence of different hardening temperatures. Other researches described dealt with an attempt to ascertain the homogeneity of iron and steel, the degree of annealing, the influence of cold-working, determination of the yield point, ultimate stress and elongation, and tests of blanks for gun barrels.

Prof. E. D. Campbell gave the results obtained at the University of Michigan during the past three years in investigating the heat of formation of the compounds of iron with carbon and silicon.

Mr. Axel Sahlin described a water-cooling device introduced by himself for protecting the walls of the lower part of the blast furnace.

Mr. J. M. While submitted a description of the new Bessemer shop and heating pits at the Barrow Hæmatite Steel Company's works. The results obtained are of interest as showing that the faster working in vogue in the United States cannot be introduced into England with advantage, for the same conditions do not apply in each country.

Mr. H. E. Wimperis, acting on a suggestion from Prof. Ewing, measured Young's modulus for a long rod by tension in an ordinary testing machine, and compared the value thus obtained with that found by experiments on pure bending. The two values differ slightly from each other, but such differences as are found may be regarded as indicating that there is no internal sliding due to layers of any impurity that may be contained in the metal.

Mr. Bennett H. Brough, the secretary, described a medal presented to the Institute by Mr. E. J. Ljungberg. It was struck in steel from the Domnarfvet Steelworks, Sweden, and is the first medal that has ever been struck in that metal. The soft basic Bessemer steel of which the medal is made contained: carbon, 0·05; manganese, 0·19; silicon, 0·007; phosphorus, 0·002; sulphur, 0·005.

Baron H. von Jüptner submitted a paper on iron and steel from the point of view of the phase-doctrine, in which he controverted some of the views elicited by the publication of the paper by Bakhuis-Roozeboom last autumn. He deals chiefly with the state of equilibrium between martensite and graphite.

The next meeting of the Institute will be held in Glasgow in September.

VITRIFIED QUARTZ.[1]

ALTHOUGH the great improvements introduced into the art of glass making by Abbe and Schott have led to marked advances in microscopy, in thermometry and in other departments during the last quarter of a century, glass is still unsuitable for many of the purposes to which we put it, and there remains a real need for some plastic material more infusible, more insoluble, more fully transparent, more elastic and more stable under changes of temperature than glass.

Such a substance exists in the form of vitrified quartz, or vitrified silica as I shall prefer to call it. Vitrified silica was first made in 1839 (*Comptes rendus*, viii. 678, 711) by M. Gaudin, who spun threads of it by hand and noticed their flexibility; and made small, very hard pellets of it by dropping fused quartz into cold water, and observed that in this form it was inactive to polarised light.[2] It was rediscovered in 1869 by M. Gautier (*Comptes rendus*, cxxx. 816), who made capillary tubes and spirals of vitreous silica and exhibited them at the Paris Exhibition in 1878, but who failed to obtain larger objects even with the aid of the electric furnace. Finally it was discovered yet once again, in 1889, by Prof. C. V. Boys, who used the torsion of "quartz fibres" for measuring small forces and produced fine tubes and small bulbs of the same material, and who was the first to fully recognise the great value of this remarkable substance.

As all who are here to-night are not chemists, I may remind you that quartz or rock crystal has for some time past been used by spectacle makers and in the construction of optical instruments; and that it is a form of oxide of silicon[1] which is very familiar to us all in the forms of sand and flint. Quartz is occasionally found in magnificent masses, but our chief source of supply is Brazil, where it occurs in large fragments like these before us on the table.

Quartz itself exhibits many of the desirable qualities enumerated above. It is hard, transparent to the ultra-violet rays, difficult to melt, a good insulator, and insoluble in most solvents, but it bears sudden changes of temperature very badly, and therefore it is not easy to manipulate quartz at high temperatures. When it has been vitrified by heat, however, it becomes much more tractable, and in the vitrified state (vitrified silica) it is not very difficult to deal with.

It is about this "vitrified silica," how to prepare it and fashion it into apparatus when plastic, and about its properties and uses that I am about to address you to-night.

The first obstacle met by those who wish to obtain vitrified silica is caused by the tendency of quartz to splinter. It will not bear contact with a flame. As you see, when a piece of quartz is thrust into a flame it cracks and falls to pieces, and the fragments again break up when similarly treated. Consequently, it was very difficult for the pioneer workers to soften their quartz in the flame. It is true that if the quartz be broken small and heated to redness in a crucible it becomes more easy to manage, but even then it gives trouble, and I should not like to say how much my first silica tube, which held about 5 c.c., had cost me for oxygen and labour when it was finished.

Fortunately we have found that we can prevent the splintering of quartz by heating it in small fragments to about 1000° C. and throwing it quickly into cold water. As you see, when this is done the quartz becomes white and enamel like, and after the treatment has been repeated the product, though still in masses, will not splinter to the slightest extent if it be thrust suddenly into the hottest part of an oxy-hydrogen flame. The preparation of this non-splintering silica constitutes the first stage of the process we are about to show you.

Another difficulty is connected with the oxy-gas burner. Vitrified silica only becomes sufficiently plastic for our purpose when it is above the melting point of platinum; and it cannot be heated sufficiently in all parts of an oxy-gas flame. What is wanted is not so much a very large flame as one which presents a very hot spot (this is situated just beyond the inner blue cone of the flame). After trying all sorts of burners I have concluded that the "mixed gas" jets give the best results, and of the burners I have tried the injector burner of Mr. Jackson, of Manchester, is decidedly the best I have met with.

The first step in the process of converting the white enamel like non-splintering silica into tubes and other vessels consists in pressing together the ends of two small fragments of the solid held in platinum forceps till they adhere, adding a third lump, then a fourth, and so on until a rough rod has been made. This rod is afterwards reheated and drawn out into finer rods about 1 mm. in diameter. In doing this care must be taken to heat each fresh mass of material slowly and from below upward in order that there may be as few bubbles as possible in the product.

A few of the fine rods of silica are next bound round a stout platinum wire, or twisted into a spiral while soft (Boys' and Dufour's method), and heated in the flame till their sides adhere. The uncouth tube thus produced is reheated, drawn out and closed at one end, a bulb is blown on the closed end in the usual manner, and this, when again drawn out, gives us a fine and fairly regular tube which can be lengthened by adding silica to one end of it, blowing a new bulb from this and drawing it out as before.

The enlargement of the small bulbs was rather difficult at first. My earliest attempts consisted in adding small lumps of silica to one end of a bulb, softening them in the flame and expanding the bulb by blowing. It is not impossible to succeed in this way, though the vessels so produced are apt to be uncouth in appearance. But the process is unsatisfactory owing to the fact that often the thinner parts of a bulb immediately surrounding the mass to be expanded become hotter and softer than the latter. When this happens the bulb bursts, and as it can only be repaired by the addition of fresh lumps of silica the process is apt to be tedious and expensive. After many failures, it occurred to me that I might develop the bulbs by applying thin rings of silica as shown in Fig. 1, heating them until the silica begins to spread

[1] A discourse delivered at the Royal Institution, on March 8, by W. A. Shenstone, F.R.S.

[2] A recent observation made by Prof. S. P. Thompson confirms this.

[1] Silicon was discovered by Berzelius in 1823.

and then expanding them by blowing. This method gave satisfactory results at once. By it we can produce long tubes and other apparatus like those exhibited to-night, if not at a very quick rate or very low cost, yet with certainty and very much more quickly than before.

When a tube of silica has been made it can be worked in the flame as easily, though not as inexpensively, as glass. Such a tube can be thickened readily by adding fresh rings of silica; it can be drawn out to various degrees of fineness and sealed hermetically; whilst all kinds of joints can be made easily. In one respect silica is easier to work than glass. It never breaks when thrust into the flame, and finished apparatus needs no annealing.

One precaution must be taken. The eyes must be protected by black spectacles. The glass of which these are made must

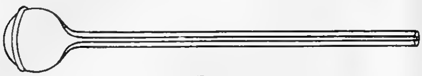

FIG. 1.

be very dark; so dark that white hot silica does not look very bright when viewed through it.

I have spoken of silica as being easy to work. I do not mean you to understand, however, that it is easy to do what you see Mr. Lacell doing to-night. It is not easy to perform any operation of this sort with his wonderful precision, and especially it is not easy to work under the conditions enforced upon him to-night, for he can see nothing of the effects he produces and must adapt his manipulations to my remarks although he can hear the latter only very imperfectly.

The Properties and Applications of Silica.

Vitrified quartz is harder than felspar, but less hard than chalcedony. When cut with a file it breaks like glass. Its conducting power for heat is about equal to that of glass. Mr. Boys has shown that, even in an atmosphere saturated with moisture, it is a very good insulator. Its density (2·21)[1] is decidedly less than that of quartz (2·66). Its optical properties have not yet been fully studied, but its approximate index of refraction has been determined by Prof. S. P. Thompson by means of a small prism cut for the purpose by Mr. Hilger. It is decidedly less than that of quartz.

The melting point of silica is not known and it is plastic over a considerable range of temperature. When a platinum wire embedded in a thick tube of silica is heated from without by means of an oxy-gas flame, the platinum melts and runs at a temperature at which the silica retains its shape.

Its rate of expansion has been studied first, by H. Le Chatelier (*Comptes rendus*, cxxx. 1703) and more recently by Prof. Callendar. The former finds its mean coefficient of expansion between 0° and 1000° to be 0·0000007, but from the manner in which his material was prepared I think it is probable that it was not quite pure. Prof. Callendar has, within the last few days, examined the behaviour of a rod of pure vitrified silica prepared by my method. He finds its mean coefficient of expansion to be only 0·00000059, which is only $\frac{1}{17}$ as great as that of platinum, and much smaller than that of any other similar substance that has hitherto been studied. He finds also that the expansion of vitrified silica is exceedingly regular up to 1000°, and that if not heated above 1000° the rod returns very exactly to its original length when cold. Beyond 1000° he found a slight permanent elongation, although the rod was under compression. Prof. Callendar was able to carry his experiments up to 1500°, which is very satisfactory, for it shows that vitrified silica remains solid, or practically solid, at this very high temperature. This is an important observation, as less carefully conducted experiments had led us to fear that it became slightly plastic even at as low a temperature as 1000°. Above 1000° the rate of expansion diminishes rapidly, changing to a contraction at about 1200°.[1] On cooling from 1500° to 1200° it expands.

Fine rods of silica and also quartz fibres are apt to become rather brittle after being heated to redness. But we have not at present detected this defect in the case of thick tubes or rods.

The transparency of vitrified silica to the ultra-violet rays has been carefully examined by Dr. A. Wynter Blyth, to whom I am greatly indebted.

The following figure (Fig. 2) illustrates very well the character of the results he has obtained. This figure gives the results of photographing electric sparks taken between electrodes made of an alloy of mercury, tin, zinc and cadmium after passing the light through sheets of quartz, vitrified silica, soda glass and flint glass. The plates of the last three substances were of equal thickness and were carefully prepared for me by Mr. Hilger.

The results show, as indeed we have found by actual experiment, that silica tubes are much more suitable than glass ones for use in studying the spectra of electric discharges.

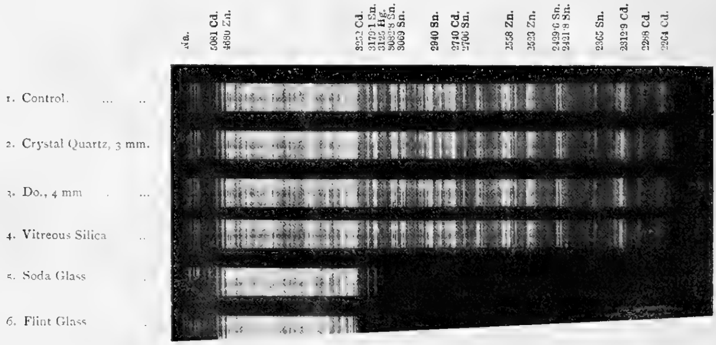

FIG. 2

The most remarkable property of vitreous silica is its behaviour under sudden changes of temperature. We have seen already that tubes of it may be plunged suddenly into an oxy-gas flame without injury, and I have mentioned the fact that apparatus made of silica needs no annealing. But this is not all; we may drop water on a white hot vitrified silica rod, or plunge white hot silica into cold water, or even, by Prof. Dewar's kind aid, into liquid air without injuring it in any way whatever; indeed, experiments seem to show that the material gains very distinctly in regard to its elasticity when it is thus treated. I need hardly point out how convenient tubes of such a material will be to

[1] This was determined by my pupil, Mr. T. Pears, the silica used contained a few minute bubbles.

[1] Le Chatelier's curve, see Fig. 3, shows a similar contraction, but commencing at a somewhat lower temperature.

chemists, or how many spoilt lecture experiments may be avoided in future by those who possess a silica tube.

This last property of silica and the splintering of quartz find an explanation in the results obtained by Le Chatelier (*Comptes rendus*, cviii. 1046, and cxxx. 1703) and by Callendar. These, as already explained (Fig. 3), show that its rate of expansion is exceedingly low, and, moreover, that at temperatures much above 1000° it contracts when heated. In these circumstances it follows, first, that the strains set up in silica when it is suddenly heated or cooled are comparatively small in amount, and, secondly, that if, for example, vitrified silica be suddenly cooled from 1500° to temperatures below 1000°, the strains set up at the earlier stages of the change must tend to neutralise those produced subsequently. These facts enabled Le Chatelier to predict, a little while ago, the indifference of vitrified silica to sudden change of temperature. But the phenomena had been observed previously and exhibited in this country.

The behaviour of quartz under changes of temperature is also peculiar. This was studied by Le Chatelier in 1889 (*Comptes rendus*, cviii. 1046). From his curves, which are given in Fig. 3, it may be seen that this form of silica expands quite regularly, and much more rapidly than vitreous silica up to 570°, but that at that temperature a sudden expansion takes place which is followed by a steady contraction on further heating.

One of the most important fields in which vitrified silica is likely to be useful is that of thermometry.

Owing to the small coefficient of expansion of vitrified silica the degrees of silica-mercury thermometers will be of greater length in proportion to the volumes of the bulbs than those of

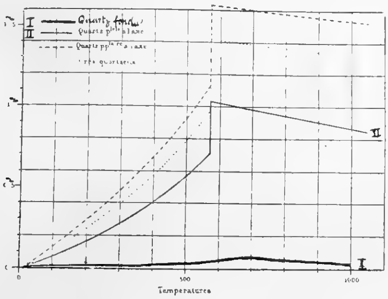

FIG. 3.

glass instruments. Owing to its high melting point it should be possible to employ it with advantage for measuring high temperatures by replacing the mercury by tin or some other metal, as has been done by M. Dufour (*Comptes rendus*, cxxx. 775). And whilst the great elasticity of vitrified silica suggests that the zero points of silica-mercury thermometers will be much more stable than those of glass instruments, the impunity with which it may be suddenly cooled from high temperatures promises obvious advantages.

Finally, the high melting point of silica should make it very valuable for use in platinum thermometers, and I exhibit such a thermometer to-night which has been fitted up for Dr. R. T. Glazebrook. But as the applications of vitreous silica to thermometry are still under investigation I will not dwell on this part of the subject except to add that, as glass reservoirs for air thermometers have proved disappointing, I am not without hopes that the new material may prove helpful in that department also.

We have not yet had time to examine the behaviour of silica with solvents, but if it acts like other forms of the same compound, it may be expected to replace platinum for some purposes, as, for example, for condensers for the preparation of pure water, and vessels of silica probably would be much more suitable for use in exact experiments on the freezing points and boiling points of many dilute solutions than the glass tubes now often used for such work. But, of course, silica vessels would be very susceptible to the action of alkalis. Finally, silica may be expected to prove superior to glass for use in researches on pure gases, owing to the qualities of its surface, and in experiments concerning the behaviour of gases at high temperatures. We have already one small application of silica to research in this latter field to put upon record. It is well known that nitrogen and oxygen enter into combination under the influence of the silent discharge, and Sir William Crookes (*Chem. News*, lxv. 301) has shown that oxides of nitrogen are present in considerable quantities in the flames which accompany the electric discharges of large induction coils; but although various observers have reported indications of the presence of nitrous fumes in the neighbourhood of flames, the forming of an oxide of nitrogen from oxygen and nitrogen alone, and without the intervention of electricity, has not, so far as I am aware, been unmistakably established. Therefore it is interesting to record the fact, first observed by Mr. Lacell, that nitric peroxide may be produced by heating a mixture of oxygen and nitrogen above the melting point of platinum in tubes of silica. It is easy to obtain a gas showing a distinctly yellow colour and exhibiting the reactions of nitric peroxide in this way.

Of course vitreous silica is not entirely without defects. Unfortunately it becomes slightly permeable to hydrogen, as platinum does, though to a less extent (Villard, *Comptes rendus*, cxxx. 1752), at about 1000°. It is attacked when hot by alkaline oxides. It may be heated to about 960° in contact with copper oxide without injury, but at higher temperatures it is attacked. It may be heated more strongly with ferric oxide, but quicklime attacks it at a bright red heat. It is evident that caution must be exercised when it is employed with basic oxides or alkaline solutions. When one first fashions vessels of silica before the flame the vessels exhibit to a greater or less extent a phenomenon resembling devitrification. They become covered with a white opaque crust. This is easily removed by reheating, provided that the tube has been kept scrupulously free from dust and dirt during the process of making it. If this be not done the appearance of the vessel may be spoilt permanently. The earlier observers attributed this phenomenon to the volatility of silica. My impression is that it is connected with the minute traces of alkaline metals present in most Brazil pebble which are usually burnt off in the processes I have described. From what I have told you to-night you will see that in several respects vitrified silica is as much superior to the best glass as Jena glass is superior to more ordinary specimens, and that the progress made in the last few years will make it possible for investigators to employ vitreous silica much more widely in the future than has been possible in the past. At the same time it is evident that the processes for producing vitreous silica are still in their infancy, that there is much more to be done and that further progress can only be made at considerable expense.

In concluding my remarks I wish to express the great obligation I am under to my friend Mr. Lacell. You will have discovered for yourselves that the chief burden has been upon his shoulders to-night, and that without the illumination provided by his precise and beautiful manipulation my discourse would have been but a dry affair. Also I must add that the cost of the work at its later stages has been aided by a subsidy from the Government Grant Fund of the Royal Society.

NOTES FROM RECENT CONSULAR REPORTS.

A REPORT on German East Africa, by Mr. A. C. Hollis, acting vice-consul at Dar-es-Salaam, and one on Veterinary Work in British East Africa and Uganda Protectorates, by Mr. R. J. Stordy, have recently been published as Nos. 2568 and 551 of the Foreign Office Series. The following notes from the reports refer to matters of scientific interest:—

GERMAN EAST AFRICA.

Locusts.—Great interest was shown in the success of the discoveries made at the Grahamstown Bacteriological Institute in the destruction of these insects, and a small quantity of "locust fungus" was imported, and has since been used on Kilima Njaro and in Usambara with success.

Caoutchouc.—There are numerous sorts of caoutchouc creepers and trees indigenous to German East Africa, but the only kinds which are of value are *Landolphia Kirkii* (Kiswahili, *Mohango*), and *Mascarenhasia elastica* (Kiswahili, *Mgora*). Until quite lately it was believed that the best rubber was the product of *Landolphia florida* var. *Comorensis* (Kiswahili, *Mbungo*), but it has now been proved that this creeper is practically worthless.

Samples of the milky juice of the wild fig tree have been sent to Europe on several occasions, but the price obtained has always been so low as not to repay the cost of transport.

Several trials have been made with other kinds of rubber. *Hevea Brasiliensis* (Para rubber) has been planted repeatedly, but without success, the climate being too dry. *Ficus elastica*, *L. Madagascariensis*, and an *Euphorbia sp.* (from Madagascar) have done fairly well. *Castilloa elastica*, *Hancornia speciosa*, and *Willoughbeia* were each tried once, but the seed did not germinate. *Manihot Glaziovii* (Ceara rubber) was first planted at Tanga in 1891. There are at present about 20,000 trees, but it is feared that it will not pay as the atmosphere is too moist. It is thought probable that Ceara rubber will do better in Donde-Barikiwa (Kilwa district), where a small experimental plantation has lately been opened.

Forestry.—The numerous rivulets and creeks, which form the mouths of the Rufiji River, and which cover an area of 100,000 acres, are lined by extensive mangrove swamps producing the timber known as *boriti*, or Zanzibar rafters. It is the opinion of various botanists that when traders—both European and native—are allowed to cut *boritis* at will, the mangroves in course of time die out, as large numbers of big trees are usually cleared from one spot, thus exposing the young plants to the direct rays of the sun, which is said to kill them. In consequence, the only trees now to be found in various parts of the Rufiji Delta are *Phoenix reclinata Osmunda sp.*, and *Barringtonia racemosa.*

In order to preserve and, if possible, to increase the present supply of *boritis*, a forest officer and three wood-rangers have been stationed in the Rufiji sub-district. The trees are felled under their supervision, and the timber is sold by the German Government.

The custom of systematically stripping a part of the bark from the mangroves, as sometimes practised in the East and West Indies, is not permitted, as it is held that such a course must be injurious to the trees. After the timber has been felled, the bark is stripped and sold.

The regulations issued for the preservation of the woods in the Usambara Hills have done much to prevent the needless felling of valuable timber. Oaks, firs and other European trees are now being planted under the auspices of the Woods and Forests Commission. Similar regulations will shortly be issued for other parts of the colony.

Roads.—Broad roads have been made all over the colony, and it is now possible to drive from Dar-es-Salaam to Lakes Victoria Nyanza and Tanganyika, from Tanga to Kilima Njaro, and from Kilwa and Lindi to Lake Nyasa.

Surveys.—A trigonometrical survey of East and West Usambara has been made, and a map of the former (Handei) is about to be printed. Much topographical work has also been done in various parts of the colony, notably in Uhehe (Hauptmann von Prittwitz), in Usagara (Dr. Stuhlmann), and between the Tanganyika and Nyasa Lakes (Dr. Kohlschütter).

A Commission for the delimitation of the boundary between the Independent State of the Congo and German East Africa left the coast for Lake Kivu in September last. On the completion of the survey of the western frontier, it is hoped that an Anglo-German Commission will be organised to delimit the boundary between the Uganda Protectorate and this colony. The frontier between the British East Africa Protectorate and German East Africa has now been finally settled. An interesting book on the geology of portions of German East Africa, by Dr. Bornhard, was published during the course of the year.

Valuable work is at present being done by Drs. Busse and Kandt. The former is making a study of all the plants indigenous to the country, whilst the latter is exploring the little-known regions between the Tanganyika and Victoria Nyanza Lakes. To him belongs the honour of having discovered the sources of the Kagera-Nile.

Dr. Maurer, after spending three years in German East Africa, has written a lengthy report on the result of his observations, which is being published by the Hamburg Marine Observatory. A successor to Dr. Maurer was appointed in October last. Meteorological observations are regularly taken at a number of places.

Museums.—A museum of products, plants and minerals was established at Dar-es-Salaam in 1899, and has since been increased in size. A collection of the lepidoptera and coleoptera of German East Africa is also being made. The ethnographical museum in Berlin has been greatly enriched by collections received from the colony.

British East Africa and Uganda Protectorates.

Tsetse Fly Disease (*Ngana*).—Mr. Stordy reports that the extent of the tsetse fly belt may be said to be from Mtoto Andei to Simba, a distance of, roughly, 90 miles. The fly is migratory in tendency, so that no well-defined line on the map can be drawn which could safely exclude the possibility of its presence. The fly, however, has never been located further inland than Muani (a halting station in the Kiu Hills on the old caravan route). When studying the causes which rendered the island of Mombasa uninhabitable for horses, Mr. Stordy ascertained that an organism, the morphology of which was identical with that found in animals suffering from tsetse fly disease, was found in donkeys which had been working for some time on the island. The disease has been practically eradicated by the advent of the Uganda Railway, with its excellent service of horse-boxes and fly-proof gauze windows.

Domestication of the Zebra.—Mr. Stordy urges the advisability of utilising for purposes of transport an animal which is naturally immuned against the ravages of the tsetse fly disease and horse sickness, such, for instance, as the zebra, of which there is an enormous number. He adds:—

"I am convinced that, should the Government enter upon a scheme for its domestication, it would prove one of great value, and that at no very distant date a supply of animals would be available, not only for African service, but also for army transport work at home or in India. The great difficulty so far has been the domestication of the adult animal. I have, however, to suggest the following plan for obtaining a possible way out of the difficulty: I would propose that a kraal be formed within a district where firearms are non-existent, as in the case of a preserve. The kraal would have two extending arms leading from the open country into it, and would be constructed large enough to hold a herd of, say, 50 adult animals. Several mounted Cape boys would be employed, whose duty, in the first instance, would be to accustom the zebras in the neighbourhood of the kraal to the sight of horses or mules. If my anticipations prove correct, the zebras will in the course of a few days follow the horses or mules, and advantage could be taken of this to lead them into the kraal. If it were, however, found that they would not be led it would be necessary to have them driven in by the Cape boys, assisted by swift-footed natives.

"The animals being in this way confined within the kraal they would naturally propagate their species. It is with the offspring that I would propose that the experiment in the way of domesticity would begin. As is well known, it has been found nearly impossible to rear a zebra foal apart from its mother. I would not propose to separate them, they would live along with and be nurtured by their mothers. A few months after birth the young animals could be caught and by various ways become accustomed to the sight and presence of man. I am very hopeful that in this way a number of young animals of both sexes would become domesticated and prove useful for transport service, and also in propagating their species. The second generation, if my experiment prove in any way successful, would be even more domesticated than their parents, and I am sure that in course of time a large supply of the domesticated zebra would be forthcoming for the future use of transport work at home and abroad. The initial cost might be a little more than the first results might justify, but there is no reason to doubt that in the long run the ultimate results would far more than compensate for the initial expenditure."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The John Lucas Walker Studentship in Pathology has been awarded to Mr. H. C. Haslam. Dr. E. S. Sladen, who has recently been serving in the Ashanti war, has been reinstated as a second student.

The board for moral science propose the assignment of certain rooms connected with the temporary pathological laboratory for practical work in experimental psychology, under the direction of Dr. Rivers.

A syndicate is to be appointed to consider the question of affording official recognition and support to the work now carried on by the Cambridge Appointments Association.

Mr. W. Bateson, F.R.S., of St. John's College, is to be re-appointed deputy for the professor of zoology and comparative anatomy during the ensuing academical year.

WE are glad to see that the London County Council has this year again arranged special beds of plants in Battersea, Ravenscourt and Victoria Parks, with a view to encourage the study of botany among pupils in elementary and secondary schools. At each of these parks about twenty beds are arranged near the paths, each bed containing specimens of a distinct order of plant, and each plant being labelled with its common name and its Latin name. In order to further assist the teaching and study of plants, arrangements have been made by which teachers may obtain orders from the Council's Technical Education Board which will enable them to secure specimens suitable for teaching purposes.

OUTDOOR work by students appears to be carried on in connection with several institutions on the other side of the Atlantic. We notice in *Science*, for instance, that the biological department of the University of California has just commenced a systematic biological survey of the coast of that state. Temporary headquarters are established at San Pedro, and the work during this summer will be carried south from Pt. Conception toward San Diego. A gasoline launch, which has been obtained for the season, will be fitted out with apparatus for dredging, sounding and making observations on temperature, salinity, specific gravity, &c. The work will be carried on by the members of the department and graduate students, together with a number of investigators who have already interested themselves especially in the west coast faunas. A party of students from Harvard University will undertake, this summer, an expedition to Venezuela for botanical and zoological research. We see also that the Mining School of McGill University will this year carry on its summer work in British Columbia. The class has just left Montreal to go out to the Pacific coast, visiting the various collieries along the line of the railway and on Vancouver Island. The party will then go into southern British Columbia for the purpose of studying the mineral deposits of the Slocan, Trail Creek and Boundary Districts, and, returning by the Crows' Nest Pass route, will visit the coal mines at Fernie Hethbridge, reaching Montreal again about the middle of June.

AT a meeting of the Court of Governors of University College, Liverpool, on Saturday last, the following resolution was passed:—"That, while gratefully acknowledging the advantages which have accrued to University College, Liverpool, by its association with the Victoria University, this Court is of opinion that a University should be established in the city of Liverpool, and will welcome a scheme with this object upon an adequate basis." In moving this resolution, Mr. Robert Gladstone, who presided, remarked that the success of the college showed the need for a University. The fees from students had increased from 700*l*. in its first year to 9500*l*. this year. Within the last few years 22,000,000*l*. sterling had been given by private individuals in the United States towards founding Universities and colleges. Was it not the duty of the wealthy people of this country to follow that excellent example? If they did not they could hardly complain if trade passed away and our prosperity diminished. We had already had a blow from German chemists. The great indigo industry in India, which had made the fortunes of many people and been a great source of trade, was threatened with extinction by chemical discoveries made in Germany. It was a misfortune they were not made in this country, as they might have been if we had been better provided with means of investigation. He hoped that the people of Liverpool who had been indifferent to the progress of the college would awake to a better state of mind, and that by their assistance they might succeed in putting Liverpool in as pre-eminent a place with regard to learning as she now enjoyed with reference to commerce.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 28.—"Further Observations on Nova Persei, No. 2." By Sir Norman Lockyer, K.C.B., F.R.S.

In continuation of previous papers, the observations of the Nova made at Kensington are brought to midnight of March 25. Since the last paper of March 7, estimates of the magnitude of the Nova have been made on ten evenings, visual observations of the spectrum on eight evenings, and photographs of the spectrum on four evenings.

Since March 5 the magnitude of the star has been gradually decreasing, but between the nights of the 24th and 25th the light of the Nova decreased very suddenly, dropping from 4·2 to 5·5 in twenty-four hours, and becoming only just visible as a naked-eye star.

The colour of the Nova has undergone some distinct changes since the observation on March 5 last, when it was shining with a clarety-red hue. On the 9th and 10th it was observed to be much redder, due probably to the great development of the red C line of hydrogen.

On the 23rd and 24th the star was noted as yellowish-red, while on the 25th (after the sudden drop in magnitude) it was very red, with, perhaps, a yellow tinge.

On March 6 the photographs were very similar to those obtained in the earlier stages, the only apparent difference being in the relative intensity of the bright hydrogen lines as opposed to those having other origins, most of which have been shown to be probably due to iron and calcium. The hydrogen lines have sensibly brightened, while the others have become much feebler.

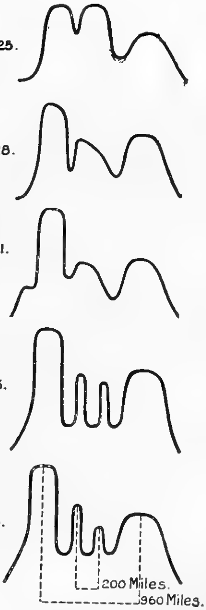

FIG. 1.—Light curve of Hβ (6-inch objective prism).

The photograph of March 10 shows a further dimming of the bright lines other than those of hydrogen.

On March 25, when the next good photograph was taken, the spectrum had undergone great modifications. The hydrogen lines are still very bright, though they do not show the structure which they did in the photographs taken between February 25 and March 10. The bright lines other than those of hydrogen, which are seen in the earlier photographs, have now disappeared, and other lines become visible. The continuous spectrum has also greatly diminished.

Approximate determinations of the wave-length of these new lines have been made by Mr. Baxandall by comparison with lines of known wave-length in the spectra of α and ε Persei photographed with the same instrument.

The lines at λ 3870 and 4650 are perhaps identical with those observed by von Gothard[1] in the spectrum of Nova Aurigæ

[1] *Ast. Phys. Jour.*, vol. xii., 1893, p. 51.

after it had become nebular, but associated with these lines in his record is the chief nebular line at 5007, no trace of which is yet visible in the photographs of the spectrum of Nova Persei. On the other hand, Hβ, which is the brightest line in the present spectrum of Nova Persei, does not appear at all in von Gothard's spectrum of Nova Aurigæ.

In the former paper the structure of the broad bright lines of hydrogen was referred to. A more detailed examination of the lines as photographed on several evenings shows that this structure has been undergoing changes.

The annexed figure (Fig. 1) gives light curves showing the variation in the loci of intensity of the line Hβ, as photographed with the 6-inch prismatic camera. These curves were plotted by Messrs. Baxandall and Shaw independently of each other, and I have satisfied myself of their accuracy. It will be seen that on February 25 there were three points of maximum luminosity, the two maxima on the blue side being of equal intensity, and greater than the third on the red side. By March 1 the centre one had greatly been reduced in intensity, and on the 3rd it had been broken up into two portions, thus making four distinct maxima.

Rough measures made on the relative positions of these points of maxima show that the difference of velocity indicated between the two external maxima is nearly 1000 miles per second, while that between the two inner maxima is 200 per second. We thus have indications of possible rotations or spiral movements of two distinct sets of particles travelling with velocities of 500 and 100 miles per second.

A similar examination of the F and G lines of hydrogen in the photographs obtained with the 30-inch reflector has also been made by Dr. Lockyer. In this longer series the most important point comes out that the maximum intensity changes from the more to the less refrangible side of the bright hydrogen line

"On the Electrical Conductivity of Air and Salt Vapours." By Harold A. Wilson, D.Sc., M.Sc., B.A., Allen Scholar, Cavendish Laboratory, Cambridge.

The experiments described in this paper were undertaken with the object of obtaining information on the variation of the conductivity of air and of salt vapours with change of temperature, and on the maximum current which a definite amount of salt in the form of vapour can carry. They are a continuation of the two researches on the same subject published in the *Phil. Trans.* for 1899.

The method employed in the experiments described in the present paper was the following :—

A current of air containing a small amount of a salt solution in suspension in the form of spray was passed through a platinum tube heated in a gas furnace; this tube served as an electrode, and the other was fixed along its axis. The temperature of the tube was measured by means of a platinum platinum-rhodium thermo-couple, and the amount of salt passing through the tube was estimated by collecting the spray in a glass-wool plug.

The variation of the current at constant E.M.F. with the temperature for air was found to be approximately capable of being represented by a formula of the type $C = A\theta^n$, where C is the current, θ the absolute temperature, and A and n constants. The constant n depends on the E.M.F. used. With 240 volts it was 17, and with 40 volts 13. The current, therefore, does not begin suddenly when the temperature is raised, but always increases regularly with the temperature, so that the lowest temperature at which the current can be detected depends entirely on the sensitiveness of the galvanometer.

The relation between the current and temperature for salt vapours was found to be rather complicated. With KI, using an E.M.F. of 800 volts, the current had the following values ($1 = 10^{-4}$ amperes).

Temp.	500°	600°	700°	800°	900°	1000°	1100°	1150°	1200°	1300°
Current	0·7	1·8	3·0	4·0	4·5	4·0	3.5	3·6	7·0	7·0

Thus the current has a maximum value near 900° C., and rises very rapidly near 1150°. Similar results were obtained with other salts.

The maximum current carried by the salt vapour (at 1300° with 800° volts) was found to be nearly equal to that required to electrolyse the same amount of salt in a solution. This fact must be regarded as considerable evidence in favour of the view that the ions are of the same nature in the two cases.

Linnean Society, April 18.—Prof. S. H. Vines, F.R.S., president, in the chair.—Mr. Harting exhibited and made remarks upon a mummified hawk from an Egyptian tomb, pointing out the difference between mummies made at Memphis, which are black, dry and brittle, from the bitumen employed in the embalming process, and those from Thebes, which, like the specimen exhibited, are of a yellowish colour, more flexible, and were prepared with natron, or neutral carbonate of sodium, Na_2CO_3, brought from the natron lakes in the Lybian desert. Colonel Swinhoe confirmed the statement that our word "mummy," Fr. *momie*, Sp. *momia*, was derived from the Arabic *moum*, wax, the most expensive process of embalming known to the Egyptians being that in which wax and bitumen were the chief ingredients.—Mr. Charles Dawson exhibited a hollow flint nodule which had been picked up on the downs at Lewes, and which on fracture was found to contain the desiccated body of a toad. The flint measured 5½ inches in length and 12 inches in circumference, and a small hole at one end indicated the point of ingress for the toad, which must have entered in a very immature condition, and died there after having attained a size too great to permit of its escape. In the discussion which followed, remarks were made by Mr. E. T. Newton, F.R.S., Mr. John Lewis, and others, the general opinion being that a modern toad had crept into an ancient flint, and, having lived for a time on such insects as found their way into the cavity, had died there.—Mr. S. Pace exhibited specimens of *Moseleya latistellata*, Quelch, the so-called "rugose coral" from Torres Strait. The specimens shown were obtained from the backs of pearl-shells collected in Friday Island passage at a depth of three to four fathoms. In the opinion of Mr. Pace they showed that the so-called coral was really a species of *Lithophyllia*.—Mr. W. B. Hemsley, F.R.S., exhibited the leaves and flowers of two new genera of Chinese trees: (1) Bretschneideria, discovered by Dr. Henry in the province of Yunnan, lat. 23° N., in forests at an elevation of 5000 feet, and bearing pink and white flowers like the horse chestnut, to which it is related; and (2) Itoa, also a native of Yunnan, growing at a similar elevation and to a height of about twenty feet. The genus, named in honour of a famous Japanese botanist, was stated to be allied to Idesia, Maxim., Poliothyrsus, Oliver, and Carrierea, Franch., all monotypic genera inhabiting China, but differing from them in certain respects which Mr. Hemsley indicated.—Mr. S. Pace read a paper on the formation and variation of the remarkable cup-shaped corallum of Turbinaria, on which no observations appeared to have been recorded. This was supplemented by a letter from Mr. H. M. Bernard, in which he offered some critical remarks on the paper which the author had previously submitted to him. Further observations on the bearing of the facts described were made by Prof. Howes.—Messrs. W. B. Hemsley, F.R.S., and H. H. Pearson communicated a paper on the flora of Tibet, based on various collections of high-level plants received at the Kew Herbarium. The country dealt with was described as lying between 80° and 102° lat. and 28° and 29° long., and having an average altitude of 15,000 feet. Within this area 360 species of vascular plants had been collected, and were referred to 144 genera and 46 natural orders. Almost all the orders represented were nearly of world-wide distribution, and none were really local. Of the 360 species only 30 appeared to be peculiar to Tibet. In illustration of the paper a selection of the plants was exhibited; most of them dwarf deep-rooted herbs, very few annual or monocarpic, and the only woody plant, *Ephedra gerardiana*, was described as scarcely rising above the surface of the ground. The majority had been collected at altitudes varying between 15,000 and 18,000 feet. Mr. C. B. Clarke, F.R.S., in making some observations on the paper, pointed out that the name "Thibet" or "Tibet" was quite unknown to the people who dwelt in the country so-called, and its precise boundaries were even still imperfectly defined. It was convenient, however, to retain a name by which it was known to so many European travellers, and the explorations and collections were making us better acquainted with the country every day.

Zoological Society, May 7.—Prof. G. B. Howes, F.R.S., vice-president, in the chair.—Mr. Sclater exhibited and made remarks on an original water-colour drawing by Sir Harry Johnston, K.C.B., of the remarkable new Mammal from the Semliki Forest in Uganda, which had been described (from fragments of skin only) under the name *Equus johnstoni*, and announced that the complete skin and two skulls from which it had been prepared were now on their way home. There could be no doubt that the animal was not an Equus, and could not be placed satisfactorily in any known genus of recent Mammals.—Dr. W. G. Ridewood exhibited and made remarks on a series of microscopic preparations of the hairs of Antelopes, Giraffe, Zebra, and the so-called *Equus johnstoni*, pointing out that the hairs of the last-named animal were similar to those of the Giraffe as well as those of the Zebra, but different from those of the Antelopes.—Mr. R. I. Pocock communicated a paper, by Mr. G. W. Peckham and Mrs. E. G. Peckham, on the spiders of the family Attidæ found in Jamaica, West Indies. It contained descriptions of thirteen new species, of which one was made the type of a new genus—Nilakantha.—Dr. David Sharp, F.R.S., communicated a paper by Mr. Peter Cameron, containing an account of the Hymenoptera collected during the "Skeat Expedition" to the Malay Peninsula. Fifty-four species were enumerated in the paper, of which thirty-one were described as new.—Dr. David Sharp also communicated a paper by Mons. Eugène Simon on the Arachnida collected during the "Skeat Expedition." It consisted of a list of the 131 species represented in the collection and descriptions of forty-eight new species and four new subspecies.

Royal Astronomical Society, May 10.—Mr. Hinks exhibited and described a new machine for measuring celestial photographs, made for the Cambridge Observatory under his superintendence, in the construction of which several improvements had been effected.—Dr. Lockyer showed slides from photographs of Nova Persei, and curves exhibiting its changes of magnitude.—Father Sidgreaves gave further results of the Stonyhurst observations of the spectrum of the Nova, which distinctly varied with the variations of its light.—Father Cortie read a paper on its visual spectrum, showing that the D lines came out strongly at a minimum, and that the spectrum resembled that of the solar chromosphere.—Prof. Turner communicated Mr. Bellamy's observations of the magnitude of the Nova and the neighbouring stars.—Mr. Wickham read the observations for magnitude made at the Radcliffe Observatory, Oxford, which supplemented and confirmed the observations made at South Kensington.—A curve made by Mr. Child was shown, exhibiting the variations in the brightness of the new star from the time of its discovery.—Observations of magnitude by Mr. Sharp and Mr. Stanley Williams were also read.—Father Sidgreaves suggested an explanation of the fact that the displacement of the lines in the spectra of new stars always indicated a rapid motion of approach.—Prof. Turner read a paper by Mr. H. C. Plummer on the geometry of the siderostat.—A paper by Mr. Franklin Adams was read on an observation of the "green flash" at sunset, a phenomenon which he considered similar to that of "Baily's beads" seen during a total solar eclipse.—Mr. Crommelin gave approximate elements of the orbit of the new comet, from which it appeared that it is moving rapidly from the sun and more slowly from the earth, and that its brightness is rapidly diminishing. Although it should shortly be visible in the evening sky it is improbable that it will be a conspicuous object.

DUBLIN.

Royal Irish Academy, May 13.—Prof. R. Atkinson, president, in the chair.—Hipparchus and the precession of the equinoxes, by Rev. M. H. Close. Hipparchus discovered the increase of the longitudes of the fixed stars, which produces the precession of the equinoxes, as we term it. That increase might be due to (*a*) the eastward progression of the stars; or to (*b*) the westward retrogression of the equinoctial points, from one of which the longitudes are reckoned; or to (*c*) both these movements existing together. We may dismiss *c* at once. Did Hipparchus believe in *a* or in *b*? Laplace, Lalande, and many others declare that he believed in *a*; Delambre, Bailly, and many others that he believed in *b*. None give any arguments for their opinions. Which are right? The former, as would appear thus: (1) Hipparchus admittedly shared the general belief of his times in the immobility of the earth. He had therefore a predisposition against *b*, which involves a movement of the earth. (2) Ptolemy's treatment in the *Almagest* of certain apparently (only) inconsistent expressions of Hipparchus on the present subject shows that he (Ptolemy), who ought to know, held that Hipparchus believed in the progression of the stars. Besides which, we have, in two places in the same work, Ptolemy's direct statement to the same effect. (3) At first, when Hipparchus had examined only certain zodiacal stars, and had observed their apparent progression, he supposed that the extra-zodiacal stars did not participate therein. But he could not have supposed this had he believed in the retrogression of the equinoctial points, for that would give an apparent progression to all the stars. He found afterwards, however, that the stars outside the zodiac preserved their positions relatively to those within, which, from his above-mentioned predisposition, would mean for him that all the stars progressed together.

PARIS.

Academy of Sciences, May 6.—M. Fouqué in the chair.—The influence of feeding, temperature, work and dust upon the evolution of tuberculosis, by MM. Lannelongue, Achard and Gaillard. A series of guinea-pigs, artificially infected with tuberculosis, were submitted to varying external conditions. If compelled to do a certain amount of mechanical work each day, the mortality increased with the amount of work done, those remaining at rest showing the most survivors. With insufficient food the effects were equally marked, those on full rations having the best chance of survival. The inhalation of dust had the same prejudicial effect as in man.—On the fourth volume of the *Annales de l'Observatoire de Toulouse*, by M. Lœwy.—M. Zeuner was elected a correspondant for the section of mechanics, and M. Oudemans a correspondant for the section of geography and navigation in the place of the late M. de Serpa Pinto.—The last sign of life; its application to man, by Dr. A. D. Waller. A modification of the method previously described, but in which the skin remains intact.—The thermal variations of waters, by M. F. A. Forel. The amplitude of the annual thermal variation is a function of the latitude. The depth of penetration of the heat is also a direct function of the latitude, amounting to about 100 metres for the Lake of Geneva, more than 150 metres for Loch Katrine, and more than 200 metres for Lakes Mjösen and Ladoga.—Application of the wedge photometer to the measurement of the photographic magnitudes of the stars, by M. B. Baillaud. The method would appear to give the most trustworthy results with stars of higher magnitudes, the measurements with the more brilliant stars not being so satisfactory.—Some new nebulæ discovered at the Observatory of Paris, by M. G. Bigourdan. A list of new nebulæ, mostly fainter than thirteenth magnitude, together with rectifications of the positions of some nebulæ previously described.—On a particular class of ruled surfaces, by M. A. Demoulin.—On the continuous deformation of surfaces, by M. G. Tzitzeica.—On Taylor's series, by M. L. Desaint.—A practical method for the correction of the secondary error of chronometers, by M. Ch. Ed. Guillaume. An application of the properties of nickel steel to the more perfect temperature compensation of chronometers.—On the existence of open currents, by M. V. Crémieu. As a consequence of the proof previously given that electric convection produces no magnetic effect, it follows that open currents ought to exist. Experiments are now described verifying the existence of these.—On osmosis through a membrane of copper ferrocyanide, by M. G. Flusin. An experimental determination of the relation between the osmotic pressure and the speed of osmosis. For solutions of saccharose, amygdalin and antipyrine the observed pressures agree satisfactorily with those calculated theoretically, none of the substance passing through the membrane. With a 1 per cent. solution of urea the observed pressure was far lower than that calculated, and in this case it was found that urea had passed through the membrane. The velocity of osmosis depends upon the thickness of the membrane, but for a given porous pot the velocities are proportional to the osmotic pressures, and hence inversely proportional to the molecular weights.—On the aluminium alloys. Combinations of aluminium with tungsten, by M. Léon Guillet. By the reduction of tungstic anhydride with an excess of aluminium a tungstide of aluminium can be isolated in the crystalline state, possessing the formula AlW_2.—On an iodoantimonide of mercury, by M. Albert Granger.—On a specimen of crystallised lime, by M. Ad. Jouve. In the preparation of calcium carbide, if the mass be cooled at the moment that the carbide commences to form, transparent prismatic needles of lime are obtained.—On the chemistry of methylene, by M. V. Thomas.—On the hydration of amylpropiolic acid with the formation of caproylacetic acid, by MM. Ch. Moureu and R. Delange. Amylpropiolic acid cannot be hydrolysed by sulphuric acid, but the reaction can be effected by boiling with caustic alkalis the β-ketonic acid, caproylacetic acid being formed.—On dimethyl-pyruvic acid, by M. A. Wahl. Of the various methods attempted to prove the constitution of this acid, the only one meeting with success was the reduction to α-oxy-isovalerianic acid by sodium amalgam.—On the anhydride of the supposed binaphthylene-glycol, by M. R. Fosse.—Action of the acid chlorides upon the ether oxides in the presence of chloride of zinc, by M. Marcel Descudé. In presence of anhydrous zinc chloride acetyl chloride reacts violently upon ordinary ether, giving ethyl acetate and ethyl chloride.—On the migration of the ternary materials in annual plants, by M. G. André. On the evolution of immature eggs of *Rana fusca*, by M. E. Bataillon.—On the development of the sole in the laboratory of Concarneau, by MM. Fabre-Domergue and Eugène Biétrix. The authors have been successful in developing soles from the eggs in an aquarium, with a mortality of only 50 per cent. They consider that their results open up the possibility of a culture of the sole commercially.—Chlorophyllian assimilation realised outside the living organism, by M. Jean Friedel.—On the movements of the soil and the formation of the valleys in Walachia, by M. E. de Martonne.—On the law of the electrical stimulation of nerves, by M. Georges Weiss. For an electrical stimulation of the nerve lasting t seconds, it is necessary and sufficient that it puts into play a quantity of electricity given by the formula $Q=a+bt$, a and b being two coefficients depending on the nerve and the distance of the electrodes. This includes the empirical formula of Hoorweg.—Researches on the injection of blood and of nephrotoxic serum in the dog, by M. Bierry.—Researches on the diseases of dogs. Vaccination of the dog against experimental infection, by M. C. Phisalix.—General characters of the teratogenous process, by M. Etienne Rabaud.—On the atmospheric dust observed at Tunis on March 10, by M. E. Bertainchand. An analysis of the red rain showed that it was essentially siliceous in character, containing only 6 per cent. of organic matter.—The movement in each synodic day of the instantaneous axis of symmetry of the barometric deviations, by M. A. Poincaré.

St. Louis.

Academy of Science, April 1.—Mr. John S. Thurman delivered an address on the many industrial uses now made of compressed air, illustrating his remarks by apparatus in operation, including electric motor air compressor, compressed air auger, drill, disinfecting atomizer, sculptors' and stone-cutters' tools, carpet renovators, &c., and a set of lantern slides showing the practical uses made of these and other implements and machines operated by means of compressed air.—Dr. Theodore Kodis exhibited, under the microscope, slides illustrating a new method of staining brain tissue, whereby, in four or five days, it has proved possible to prepare single or double stained preparations containing nerve cells with the dendrides of the latter brought out by a direct stain, instead of being differentiated merely as amorphous silhouettes, as is the case with the much slower Golgi process commonly employed. It was stated that the material is treated before sectioning, for about twenty-four hours, with cyanide of mercury, followed for approximately the same length of time by a formaldehyde solution, after which sections are cut, stained with phospho-molybdate hæmatoxylin and, if desired, a contrasting stain, such as one of the aniline greens, and mounted in the usual way.

DIARY OF SOCIETIES.

THURSDAY, May 16.

Chemical Society, at 8.—The Nutrition of Yeast, Part III.: Dr. A. L. Stern.—Derivatives of Methylfurfural: H. J. H. Fenton and Miss Mildred Gostling.—The Preparation and Optical Inversion of Optically Active Nitrogen Compounds, dextro- and Lævo-α-benzylphenyl-allyl-methylammonium Salts: W. J. Pope and A. W. Harvey.

FRIDAY, May 17.

Royal Institution, at 9.—Turkish Kurdistan: Earl Percy.
Society of Arts, at 8.—Polyphase Electric Working: A. C. Eborall.
Epidemiological Society, at 8.30.—What is Plague: Dr. Klein, F.R.S.

SATURDAY, May 18.

NATIVE RACES AS IMPERIAL PROBLEMS.

The Natives of South Africa; Their Economic and Social Condition. Edited by the South African Native Races Committee. Pp. xv+360. (London: John Murray, 1901.) Price 12*s.* net.

BY far the most serious of all the questions confronting us in South Africa is the question of the native races. The reason is not far to seek. Two at least of the African races are endowed with extraordinary vitality. The Australian aborigines are a people which will neither thrive in the presence of the white man nor be absorbed into his hosts. They are, therefore, bound to die out in the presence of civilisation, and, however much we may regret it from philanthropic or scientific motives, the political and social problems involved will sooner or later cease to exist. It is otherwise with the Negroes and the Bantu. These two prolific races show no signs of decay when brought in contact with civilisation. On the contrary, their intestine wars and savage practices being put an end to, they increase rapidly in number.

The Negro is not found in South Africa. There the bulk of the native population is Bantu. The remains of the earlier peoples, Vaalpens, Bushmen and Hottentots, are (save the last named) of no political importance. They are, indeed, of considerable scientific interest. The Vaalpens, a black pigmy race dwelling in caves and holes in the Northern Transvaal and the Bechuanaland Protectorate, have never yet been subjected to scientific investigation. They are said to practice cannibalism, and to be the true aborigines. The Bushmen, of larger, though for the most part still diminutive, stature, are, like them, savages of a low type. They display, it is true, some advance on the Vaalpens, and are specially noted for their extraordinary skill in drawing. They are of a yellowish-brown colour. In this and some other physical characteristics they resemble the Hottentots, who, it has been conjectured, are the result of a mixture in blood of the earliest Bantu immigrants with the Bushmen. For the most part the Hottentots have come under the influence of civilisation, though there are communities of them still practising their own customs. The Bushmen are hunters. They have hardly yet taken the first step towards civilisation, in the shape either of agriculture or of herdsmanship. The Hottentots, on the other hand, are a pastoral people, while the Bantu in all their branches both keep cattle and are acquainted with rudimentary agriculture.

The Bantu are divided by Prof. Keane into three groups. The first consists of the Zulus and the tribes connected with them, such as the Ama-Xosa, the Matabele and the Kafirs. The second consists of the principal inhabitants of the Orange River Colony, the Transvaal, Basutoland and Bechuanaland, namely, the Basuto and Bechuana. The third includes the Amatonga, the Swazis, the Fingoes, the Mashona, Makalaka and other tribes, representing, according to Prof. Keane, "the first wave of Bantu immigration." This of course assumes that the Hottentots are not to be credited with Bantu blood, but are an offshoot of some other African stock.

In consequence of their overwhelming political and social importance, the work before us, though bearing a wider title, relates almost entirely to the Bantu. It is in substance a plea for a full official inquiry into the circumstances of the native races, with a view to framing a sound policy in dealing with them. We are first presented with a short account of the various peoples which, though taken from the best sources, shows very clearly how defective our knowledge is. In this account an estimate of the populations and a general outline of native laws and customs are included. We are next told on what terms we hold the different provinces of British South Africa. This is important, because our titles to all the provinces are not the same. The most extreme advocate of the right of the white man to the lordship of the world would probably admit there was a distinction to be drawn between cases in which we hold by right of conquest, either directly from the natives themselves or from those who had conquered them, and cases in which we simply administer the country by invitation of the natives. In the latter it is evident that every principle of justice requires us to treat the land as still their property and, regarding them as the true owners of the country, to administer it for their benefit.

These preliminary matters, necessary for the understanding, or at least for the setting in proper perspective, of what follows, having been disposed of, we approach the main subject of the book—the relations of the native population to their white rulers and to the white colonists in general. They are considered under the heads of (1) land tenure; (2) labour supply, occupations and wages; (3) the law of master and servant; (4) the compound system; (5) savings banks and labour agencies; (6) the pass laws; (7) education; (8) taxation; (9) franchise; and (10) the sale and supply of intoxicating liquors. It is not my intention to follow the writers in their review of these matters. Deeply interesting as they are, their interest is rather political and philanthropic than scientific, and so far it is foreign to this journal. It must suffice here to say that these chapters have been compiled with care from information supplied largely at first hand by correspondents (of whom a list is given) and by official and other documents; they are marked by sanity and moderation, and are written with the object, not of dogmatising on questions bristling with difficulty, but of collecting and presenting information.

The importance as well as the difficulty of the problems involved is evident. The total native population is estimated by the editors at about five times the numerical strength of that of the whites, and it is rapidly increasing. The natives are not allowed to indulge as they once did in intertribal wars, which would not only give them occupation but keep down their numbers. They are not at present fit for continuous labour. The habit of work is a growth of civilisation, and cannot be imposed as you put a coat of paint on a door. Generations are required to raise a people from savagery. It is no wonder, therefore, that the increase of their numbers and their idleness are sources of anxiety to the intrusive colonists. Various expedients have been tried. The Boer policy was first massacre, then slavery, cruelty and oppression. Nor have our own people always been guiltless in this respect. The results have been lamentable alike to the natives and to the Europeans. With the abolition of slavery a more humane policy on the part of the Government was inaugurated. But neither the Home Government nor the Colonial Governments have been invariably wise or consistent. Though on the whole their efforts have been honestly directed to the benefit of the natives, the conflicting interests of natives and colonists have often caused, and still cause, grave difficulties. The experiment has been made in Cape Colony and, to a more limited extent, in Natal, where the native question is more acute, of admitting natives who fulfil certain stringent conditions to the franchise. The numbers admitted are not yet large, but it is obvious that the principle thus introduced may involve consequences which cannot at present be foreseen.

Accordingly, the editors are abundantly justified in their belief that the time is opportune to consider our policy towards the native races throughout British South Africa. The information elicited by their inquiries is not exhaustive; it is only preliminary. One of the chief results has been the discovery how little we know about the natives and their needs. This is a point which the editors press again and again. In August last they presented a memorial to H. M. Secretary of State for the Colonies, urging the expediency of inquiries on the laws, customs, land tenure and tribal system of the natives, and on the other points dealt with in these pages. At that very time, as the readers of NATURE know, the Anthropological Institute and the Folklore Society were independently presenting a joint memorial making a similar request. The history of Christian missions, the history of every attempt by Europeans to rule a savage or barbarous people, is full of failures and bloodshed attributable to imperfect comprehension of native customs and ways of thought. So long as the missionary societies and the Colonial Office agree in ignoring the necessity of anthropological studies these failures will be repeated. In 1881, however, the Cape Government awoke to the desirability of ascertaining and recording some facts concerning native customs. A Commission was appointed, and its Report is, so far as it goes, an extremely valuable document. "There is urgent need," say the editors of the present volume, "of a similar inquiry covering the other territories of South Africa under British rule." When this protracted war has ended we shall have to make new laws in the Transvaal and the Orange River Colony to control the relations of the black men to the white, and of the black amongst themselves. We cannot legislate without first knowing the existing facts. A Commission of Inquiry would therefore seem inevitable. If it be determined on, it is to be hoped that scientific assistance will be called in, with a view to rendering the results complete and trustworthy, and, further, that it will be found possible to extend the area of its inquisition to Bechuanaland and to Rhodesia. That such an inquiry, if adequate in scope and properly directed, will incidentally be of high value to various departments of science (notably, but not exclusively, to anthropology) is an additional reason for the appointment of the Commission. In the pages of "The Natives of South Africa" scientific considerations are not adduced; but even without them the book is a powerful plea for inquiry, and one which may be heartily commended to all who are interested in the serious questions it presents for solution.

The Committee have given an interesting and useful appendix of selections from their correspondents' replies, and three maps showing the distribution of population in Cape Colony and Natal. Quite as necessary as either of these maps is one or more showing the locations of the different tribes in all the territories. These should have been given. Many of the tribes can certainly be located. If all cannot be, the defects would have been a striking illustration of the state of our ignorance.

E. SIDNEY HARTLAND.

PROGRESS IN THE COMING CENTURY.

Twentieth Century Inventions: a Forecast. By George Sutherland, M.A. Pp. xvi+286. (London: Longmans and Co., 1901.) Price 4*s.* 6*d.* net.

THE *rôle* of prophet of the industrial development ot the discoveries of science is one not lightly to be assumed, especially if it is the aim of the prophecy to cover so long a period as a hundred years. Mr. Sutherland has, nevertheless, had the temerity to attempt this task, and to approach it in the spirit of the man of science deducing logical conclusions from definite data rather than in that of the writer of fiction giving free rein to his imagination. We are not sure whether, when a century is concerned, the imaginative method, if kept within proper bounds, is not almost as satisfactory as the other. The predictions of the novelist are often fantastic and wild; but if he is likely to overshoot the bounds of probability his more cautious brother prophet is almost certain to fall short of them. The system of the logical prophet has, indeed, an inherent defect—it can only foretell the development and further application of knowledge that has already been acquired, and cannot take into consideration the possibility of the discovery of new facts. Yet it is by discovery as much as by invention, if we may draw a distinction between the two, that progress has taken place in the past, and it is to be hoped, for the sake of science, that the same will be true in the future. No prophet writing in 1801 on the same lines as Mr. Sutherland could have foretold the present development of electric traction, for he could not have foreseen the discovery of electro-magnetic induction made by Faraday thirty years later. He might, however, have predicted the modern railway systems, because the essential principles of these systems were already known. It would be easy to multiply instances, but we think it is evident from what we have said that Mr. Sutherland's prophecy must in some respects fall short of the truth, unless, indeed, the coming century is to be devoid of discoveries.

But if Mr. Sutherland's system is open to objection on the grounds that have been stated above, it has also much to recommend it. It would be idle to devote time to the serious consideration of extravagant predictions of the purely imaginative writer whose prophecies must be judged by their consistency and their power to interest. With the forecast in the book before us it is different; it is well considered and carefully thought out, and affords material for thoughtful, and very possibly useful, reflection. It is of interest to all those who are engaged in helping onward modern industrial development to pause occasionally and look somewhat far ahead to see in what direction that development is tending. Those who wish to take such a journey into the future cannot do better than make it under Mr. Sutherland's guidance. He points out clearly, and in many cases we think rightly, what are likely to prove the most important inventions in the twentieth century. It is, perhaps, necessary to state that the author counts inventions as belonging to the period during which they come to fruition rather than to that in which the original idea is first conceived; some such limitation is certainly necessary, otherwise there will never be wanting those who will be ready to prove that there is nothing new under the sun, and that the germ of the *Turbinia* was contained in Noah's Ark.

A great deal of space is justly given to the generation, storage and distribution of power. This is becoming one of the most pressing problems of the immediate future, as is evidenced by the number of big power schemes now on foot. We already see the new industries requiring much energy congregating around large sources of water-power. This source has only just begun to be seriously tapped, and for a time, at least, we can regard it as an almost inexhaustible supply of cheap power. But as progress goes on, as these industries develop and increase, water-power will no longer remain so cheap, for land will get more valuable in the neighbourhood of suitable waterfalls, and the available power will be, sooner or later, all in use even though the falls possess so large a reserve as Niagara. We shall then have to turn to other sources as yet untouched; it is to the winds and the waves that we shall go for help, according to Mr. Sutherland. Such sources as these, however, are intermittent and can only be useful when a thoroughly satisfactory means of storing power has been found. For this we must look to the electric accumulator, especially as the electrical seems to be the most suitable method of transmitting power. The author enters into detail at considerable length concerning the inventions by means of which the wind and wave power will be "cabin'd, cribb'd, confin'd," and here we must confess we do not think him so convincing. Throughout the book there is a tendency to enter into too minute details; it will be long before many of the problems are seriously attacked, and by the time they are it is probable that we shall have better means of attacking them than are now at our command.

Transport, both by sea and land, is another very pressing question. It is being very generally recognised that some method of relieving the congestion of the towns must be found, and it is probable that this will be most readily effected by increasing the ease of locomotion, though the transmission of power, by taking the work to the labourer in place of bringing the labourer to the work, will no doubt be a great help. Mr. Sutherland's schemes for increased facility of transport by road and rail are, many of them, suggestive and will be read with interest.

Space forbids our following Mr. Sutherland further into the coming century. We are inclined to disagree with his predictions concerning the future of music, art and many of the minor applications of electricity. We do not, for example, believe that wireless telegraphy will ever be used for lighting (and we suppose laying) the morning fire, that the housemaid of the future may not have to come down to a cold room. But, on the whole, the book takes a comprehensive and broad survey of the probable progress of invention, and is well worth careful reading.

VERTEBRATE HISTOGENESIS.

Lecithoblast und Angioblast der Wirbelthiere. By Wilhelm His. Abhandlungen der math.-phys. Classe der Kgl. Säch, Gesell. der Wissenschaft, vol. xxvi. pp. 173-328; 102 figures. (Leipzig: 1900.) Price Mk. 8.

THIS memoir is the latest and largest of a series, published by the author in the *Transactions* of the Saxon Academy of Science. Its title indicates that it treats of histogenetic studies in those parts of the developing germ which are concerned in the formation of the blood-vessels and blood, and in the elaboration and assimilation of the yolk-mass. The table of contents at the close reveals a very much wider sphere of research than that suggested by the title. It is, indeed, a treatise on histogenesis. Prof. His himself describes it as a sort of histological testament. Like some other documents of the like name, it contains very varied provisions. Almost all the phenomena witnessed in the early development of the embryo are treated of at greater or less length, the first blood-vessels and blood and the changes undergone by the yolk and its components receiving special attention. The work is full of detailed observations, and these are described at the hand of a complex terminology.

Following the plan of certain of his previous studies, the author has departed from the usual custom of gathering the illustrations into plates. And there can be no question that the numerous woodcuts woven into the text add greatly to the usefulness of the memoir. If the work contain no strikingly novel or fundamental discovery, it may none the less be described as a valuable storehouse of exact observations for the use of future investigators.

One of Prof. His's most remarkable recent discoveries —originally published in an earlier study—is again dealt with in connection with the yolk-germ or lecithoblast. It is that, underlying the so-called amitotic or direct division of the yolk-nuclei or merocytes, there is a modification of ordinary mitosis, *i.e.* a pluripolar form. This identification is probably to be regarded as among the greatest real advances in cytology of recent years. For does it not bring the unknown and incomprehensible into relationship with the known?

It may, however, be doubted whether, as the author maintains, the products of pluripolar mitosis—if the process attain any particular complexity—are ever able to revert to the bipolar form; indeed, whether cells which have got entangled in this complex network are ever able to emerge therefrom as normal entities. Connected with this question there is also the curious amœboid mode of yolk-annexation by certain cells described and figured in the memoir. Rueckert demonstrated some years ago—and his observations have recently been fully confirmed by Beard—that a tendency to free themselves from the yolk is often one of the characteristics of cells undergoing pluripolar mitosis. Like the latter process, that recorded by His as yolk-annexation would therefore be classifiable as a degenerative phenomenon.

The task undertaken in these histogenetic studies was an immense one—even for an investigator of the energy and talents of Prof. His—covering, or attempting to do so, a large portion of the field of developmental mechanics. How is it that certain structures arise at certain, usually predestined, times in particular places, and only there and out of certain cells alone? The simplest answer, and that long made the basis of almost all embryological research, has been that out of three primary layers of cells the embryo and all its parts take their origin. The working out of the details has largely been the labour of embryological investigation of the past fifty years.

The wealth of observation contained in the present memoir furnishes ample evidence that after all progress has been exceedingly slow.

We still do not know why a certain cell becomes a gland-cell, another a ganglion-cell: why one cell gives rise to a smooth muscle-fibre, while a neighbour forms voluntary muscle. The prolonged researches of Prof. His, often of far-reaching import, and always carried out with exceeding care, afford typical instances of investigation on the lines of development by epigenesis. The author himself states that as a solution of all, or even many, of the great problems of histogenesis they have disappointed his hopes.

It would appear to be quite possible that numbers of embryological problems incapable of any fundamental solution may exist. The range of human mental vision may have been reached with the limitations of microscopic lenses. However that may be, it is daily becoming more apparent that epigenesis with the three layers of the germ furnishes no explanation of developmental phenomena.

"There is no coming into being!"—"Es giebt kein Werden"—wrote Haller long ago. And this is emphasised by Weismann when he informs us that an epigenesis is an impossibility. But there is an evolution or unfolding. Development, even in lowly forms of animal life, is a complicated study. With three germ-layers as its basis no advance in its interpretation is possible. Nothing like all the cells present at the close of the egg-cleavage are destined to share in the formation of the future embryo. Many of them—often the majority of them—are merely larval or transient in character. Still others, the greater number of those remaining, are charged with the duties of handing on the "stirp," in Galton's sense, to future generations.

The chain of life from generation to generation is of exceeding intricacy. The unravelling of the tangle and the true interpretation of the many important links in it both serve to increase the magnitude of the embryologist's task. The day is not yet when this approaches completion.

OUR BOOK SHELF.

The Scientific Memoirs of Thomas Henry Huxley. Vol. iii. Edited by Sir Michael Foster and E. Ray Lankester. Pp. xi + 622. With thirty plates, maps and text illustrations. (London: Macmillan and Co., Ltd., 1901.) Price 30*s.* net.

THIS magnificent volume will be to the working naturalist the most welcome of the three now published. It contains 38 memoirs, papers and addresses, covering, in all, 608 pp., as against 50 with 508, and 37 with 591 for volumes i. and ii. respectively. It embodies the scientific work of Huxley at his best. As memorable may be cited the great memoir on the bird's palate, which marked an epoch in comparative osteology; and that on the ossicula auditus, in which recent research has discovered a hidden treasure, and of which one of the leading conclusions, viz. that of the primary nature of the union between the hyoid and the columella auris, has but lately been shown (long opposition notwithstanding) to be developmentally confirmed. Particularly noteworthy are the series of memoirs and papers upon the Dinosauria, and the series of addresses and philosophic memoirs on the ethnology, archæology and distribution of mankind in various parts of the globe, which will ever rank among their author's best achievements.

As regards the general get-up of the book, the editors have spared no pains to render perfect their labour of loyal devotion. One or two of the plates are, perhaps, a little lacking in sharpness—printed, in the copy before us, a little lightly—but all that is important is definable.

It is with a feeling of considerable relief that we note the incorporation of the Geological Survey memoir upon the Structure of the Belemnitidæ; for this, in respect to certain details, contains the most accurate description to-day available, and will ever hold its original high place in the literature of zoology. Our expression of relief is due to the fact that this great essay, together with five of those afore-mentioned in anthropology, the two papers upon the lowly plant organisms which close the present volume, and one or two other items, were entirely omitted in the first-published table of "contents," put into circulation on the announcement of the work. The reason for this is not difficult of demonstration, and while we would convey to the editors our gratitude for having, as their labour advanced, made perfect the definitive list up to the period embraced by the present volume, we would remind them that, so far as the said "contents" table affects the volume to come, the great Survey Memoir on the Elgin Crocodilia, the Rede Lecture on Animal Forms, delivered at Cambridge in 1883 and duly reported at some length in our own pages (NATURE, vol. xxviii. p. 187), with the "Further Notes on Hyperodapedon" (*Quart. Journ. Geol. Soc.*, vol. xliii., which was the last zoological paper that issued from Huxley's hands, were similarly not included.

In the production of this monumental series of volumes, publishers and editors are incurring a debt of gratitude on the part of the present and future generations; and carrying out a labour of love in a spirit becoming in its dignity the original memoirs themselves.

Fact and Fable. By Effie Johnson. Illustrated by Olive Allen. Pp. 117. (London: Chapman and Hall, Ltd., 1901.) Price 6*s.*

THIS is a pleasingly-written and attractive little book, containing a series of short tales and sketches, the first and largest of which relates a boy's visit to an ant-hill, his adventures, and what he found there. Another tale relates the adventures of a young bee; while most of the others consist of allegorical or symbolical presentations of various phases of human life. As the authoress admits, the descriptions of the events in ants' nests are taken from different species, and the large queen is a Termite. But the story may serve to interest young readers in ant-life and lead them to read other books on the subject.

Science and Mediaeval Thought. By Prof. T. Clifford Allbutt, F.R.S. Pp. 116. (London: C. J. Clay and Sons, 1901.) 2*s.* 6*d.* net.

THE brilliant character of the Harveian oration delivered before the Royal College of Physicians last October by Prof. Clifford Allbutt could be judged by the abridgment which we published a few days after the delivery of the address (vol. lxii. p. 630, October 25, 1900). The complete address is given in the volume before us, with a few additions and notes, and we cordially commend it to every one who desires to read an inspiring account of the evolution of mediæval into modern thought.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On a Form of Artificial Submarine Cable.

IN order to illustrate the effect which capacity has on the sending of arbitrary electrical disturbances along a conductor, Mr. C. F. Varley, about the year 1860, devised an artificial submarine cable equivalent in its action to a real cable long enough to reach from England to Australia. For obvious reasons such a device would be a most instructive piece of lecture-table apparatus.

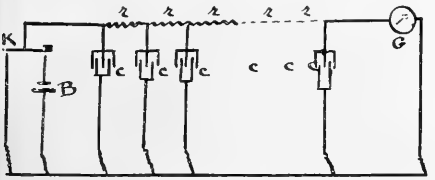
The so-called "K.R. Law" of Lord Kelvin states that the time-lag in signalling over a cable is proportional to the capacity of the dielectric sheathing per unit length, to the resistance (also per unit length), and to the square of the length.

Thus in order that the time-lag of an artificial cable shall be great, both the resistance and capacity must be great. The first of these two conditions is, of course, easily fulfilled, but if the ordinary tin-foil type of condenser is used as the capacity, both the bulk and cost of the apparatus is very considerable.

For this reason very few artificial cables have been made after Varley's plan. I have recently made an artificial cable, giving about six seconds time-lag, which is entirely free from the disadvantages just mentioned, and for this reason I trust that it may commend itself to teachers of physics as a piece of demonstration apparatus.

In an actual cable the capacity is distributed uniformly along the length of the line, but in an artificial cable of great equivalent length the capacity must be distributed non-uniformly in some such way as that shown in the accompanying figure.

In it B is the battery, K a double key so connected as to put the cable either to the ungrounded pole of the battery or to



Earth.

earth, *r r* are a number of high resistances which play the part of the conducting core of the cable, and *c c* are the capacities which play the part of the insulating sheath of the cable. G is the galvanometer, one side of which is connected to earth, and forms the receiving end of the apparatus.

This is substantially the arrangement which Varley used, the only difference between his artificial cable and mine being that I have substituted light, easily made electrolytic capacities for the bulky, expensive commercial capacities used by him.

As is well known, the polarisation capacity of platinum electrodes in dilute sulphuric acid is very great. Unlike true dielectric capacity, it is not independent of the charging potential, its value increasing with the charging potential and reaching a value as high as 500 micro-farads per square inch of electrode surface.

Even though the capacity of such a cell is not a fixed quantity we may make use of its great value in constructing an artificial cable, though, of course, we are then obliged to use a battery at the sending end having an E.M.F. less than the maximum polarisation of the electrolytic cell.

The capacities I used were made by fusing platinum wire into the ends of little cells made of glass tubing. These were filled with water and a piece of platinum foil was corked into each so as to dip a few millimetres into the water.

I made thirty-six such cells and mounted them on a board in which holes were drilled to allow the platinum wires to project through so that they might dip into a trough filled with mercury which was connected to earth. These thirty-six cells were divided into twelve sets of three cells in parallel, and each of the twelve sets were connected in the positions *c c* of the figure. The resistances *r r* aggregated about a million ohms.

The advantage of mounting the cells on the board as described is that the action of the cable when the platinum wires are in the mercury (and hence the capacities in, as shown in the figure) can be rapidly compared with the action when the capacities are out. In the latter case the apparatus represents an overhead line of resistance equal to that of the cable.

With the apparatus as described the galvanometer responds as soon as the key is closed in case the capacities are out, but if they are in there is a time-lag of about six seconds.

A. TROWBRIDGE.

Physical Laboratory of the University of Wisconsin, U.S.A.

Electro-Chemistry.

MY attention has lately been directed to your review of my book on "Practical Electro-chemistry" (April 18, p. 582). I desire to thank you for noticing a modest effort at length. Your reviewer is in error in supposing that the series system of copper refining is now of any commercial importance. The process was founded on a delusion and is dead. The working up of anode sludge, mentioned by your reviewer, is a purely chemical question and does not fall within the scope of the book. I note with interest that a method has been devised for refining tin, but I do not anticipate its general adoption; gold and silver being absent from crude tin it is hardly to be expected that the anode sludge obtained in the process of refining will be worth exploitation. The electrolysis of chlorides to produce chlorates is an important branch of electro-chemical industry, and omissions of details in my book, quite fairly remarked by your reviewer, are due less to indolence on my part than to the impossibility of obtaining authentic information. Manufacturers, even in the United States, where a liberal spirit prevails, are chary of allowing entry to their works. A somewhat persevering inquiry at Niagara convinced me of this reluctance. But in spite of this difficulty I am well assured that the competent chemist, equipped with a sound knowledge of the principles of electrolysis, need not fear to engage in the practice of this the latest and most promising of industries.

BERTRAM BLOUNT.

Westminster.

WITH reference to Mr. Blount's letter—if the "series system" of copper refining was "founded on a delusion" it appears to have been a fairly successful delusion. If Mr. Blount consults "The Mineral Industry" for 1899 he will see that the Baltimore Copper Smelting and Rolling Co., which uses this system, turned out between 60 and 70 million pounds of refined copper in 1898. The Nichols Chemical Co., N.Y., whose daily output of refined copper amounts to 60 tons, also employs this method (or did in November 1899).

Mr. Blount further states that gold and silver are absent from tin and therefore "it is not to be expected that the *anode sludge* obtained in the process will be worth exploitation." Mr. Blount is probably thinking of Cornish tin, but Mr. Claus's process has been devised for purifying South American tin, some of which contains considerable quantities of gold and silver, *e.g.* an *anode sludge* analysed for Mr. Claus contained 698 ozs. silver and ½ oz. gold per ton (1 ton of *anode sludge* would be obtained from about 10 tons of crude metal). In another analysis the crude anode gave 7 ozs. silver and 1 oz. gold per ton.

I am still of the opinion that Mr. Blount would have considerably added to the value of his book had he described in detail the working up of a "typical" anode sludge. The successful treatment of the sludge is extremely important to the practical electro-chemist, and if a description of it is outside the scope of a book devoted to electro-chemistry, I fail to see in what book it should be described.

In the third place I did not accuse Mr. Blount of being "indolent"; if he were so he would not sit down and write a book of nearly 400 pages. An author must of necessity use his own judgment, as to what he will include and what he will reject, in writing a book. It does not, however, follow that the reviewer will agree with him.

F. MOLLWO PERKIN.

Specimens of "Aecidium berberidis."

THERE is a barberry bush near where I live which usually bears on its leaves a number of cluster cups (*Aecidium berberidis*). They are just appearing.

Perhaps some of your readers might care for a few specimens. If so, and if they would communicate with me, I should be pleased to send them a supply.

J. LEWTON BRAIN.

Swanton Morley, Dereham, May 20.

THE BRITISH ASSOCIATION MEETING.

THERE is every indication that the coming meeting at Glasgow will be an unusually large one, and the local committee is putting forth every effort to make it a success in every way.

The last meeting in Glasgow was in 1876, under the presidency of Dr. Andrews, F.R.S., professor of chemistry, Queen's College, Belfast, and the attendance was 2774. At that date the population of Glasgow was about 500,000, and now it is considerably more than 760,000, or, including the neighbouring burghs, about one million. But the expectation of a large meeting is based, not only on the increased population, but also on the increased attention paid locally to scientific pursuits and to the circumstance that an International Exhibition of Industry, Science and Art is being held in the Kelvingrove Park, adjacent to the University Buildings, where all the sectional meetings are to take place.

Four very important additions have been made to the buildings of the University since the Association last met in Glasgow. The Bute Hall is to be used as a reception room, and from its position and size it lends itself admirably to that purpose. Large and commodious anatomical rooms have been completed, and separate handsome buildings for botany and engineering are expected to be finished in time for the meetings. Thus, in the class-rooms of the University, there will be ample room for all the section meetings and conferences. The first general meeting will be held at 8.30 p.m. on Wednesday, September 11, in the St. Andrews Hall, when the president-elect, Prof. Arthur W. Rücker, Sec.R.S., will deliver the opening address. In the same hall, which will accommodate considerably more than 3000 persons, the Friday evening lecture will be delivered by Prof. William Ramsay, F.R.S., and the Monday evening lecture by Mr. Francis Darwin, F.R.S. The Saturday evening lecture to workmen will be delivered in the City Hall by Mr. H. J. Mackinder.

On Thursday evening, September 12, the Corporation of the City of Glasgow will give a conversazione and reception to the members in the City Chambers, and on Tuesday evening, September 17, the Executive Council of the International Exhibition will give a conversazione and reception in the Fine Art Galleries within the Exhibition grounds. This building is considered to be one of the finest in this country and consists of a central court, 125 feet by 56 feet, with two courts, each 102 feet by 60 feet, east and west of the hall; also twelve galleries averaging 100 feet by 28 feet, aranged in two floors around the courts. The collection embraces the following divisions :—

(1) Oil-paintings of the nineteenth century.
(2) Water-colour paintings of the nineteenth century.
(3) Sculpture and architecture.
(4) Works in black and white.
(5) Photography.
(6) Art objects.
(7) Scottish archæology and history.

The conversazione in the Art Galleries will therefore be of special interest.

The Royal Scottish Society of Painters in Water Colours will give a conversazione on September 18, and the Faculty of Physicians and Surgeons will give a dinner to the medical members of the Association on September 16; and other public bodies in the city are expected to cooperate in a similar manner. Lord Overtoun has kindly offered to entertain the members at a garden party at his seat at Overtoun, Dumbartonshire, probably on the afternoon of Monday, September 16; and another garden party will be held in the Botanic Gardens on the afternoon of Friday, September 13.

Excursions are limited this year to Saturday as, by resolution of the general committee, the local committee has been requested not to arrange for any whole day excursions on Thursday, September 19. On Saturday, September 14, there will be excursions to :—

1. Loch Lomond, where the party will be entertained to luncheon by the kind invitation of the Duke of Montrose, Lord Overtoun, Sir James Colquhoun of Luss, Mr. Crum Ewing of Strathleven, Dr. Jacks of Crosslet, Mr. Campbell of Tullichewan, and others.

2. The Roman Camp at Ardoch, Doune Castle and Dunblane Cathedral, where the party will be entertained by Sir James Bell, Bart.

3. Craignethan Castle (Tillitudlem), Lanark and Falls of Clyde, where the party will be entertained to luncheon by the Right Hon. the Earl of Home.

4. Stirling, where the party will be entertained to luncheon by the Town Council of Stirling.

The Howieton Fishery Company has kindly agreed to allow the excursionists to inspect the interesting fish ponds at Sauchie.

5. Paisley, including visits to the Abbey, Coats Memorial Church and Paisley Thread Works, where the party will be entertained by Sir Thomas Glen Coats.

Other excursions are in contemplation, including a sail down the river; but the arrangements have not yet been completed.

A large number of the clubs and libraries in Glasgow have kindly agreed to admit non-resident members as honorary members on presentation of their membership tickets. Full particulars of these will be given to members in the reception-room.

Glasgow, being situated in a district rendered famous by the genius of romance, and still more famous as the theatre of many of the most thrilling events in Scottish history, is well known to be the seat of some of the most extensive trading and manufacturing interests of the country; its engineering and shipbuilding works, its cotton and chemical manufactories and its iron trade are world famous. Arrangements are being made to allow members to visit some of the more important establishments at stated times during the meeting, including engineering works, shipbuilding works, ironworks, mills, locomotive works, printing works, pottery manufacturing, chemical manufactories, &c.

In 1876, when the Association last met in Glasgow, the local committee prepared three handbooks, which have remained until the present day as valuable books of reference for men of science and other students of the fauna, flora and geological features of the Clyde district. Following this precedent, the local committee for this coming meeting is also preparing three handbooks. The first is to deal with the general industries of Glasgow and the Clyde, and will deal with, among other subjects :—

(1) Mining and Quarrying, by Mr. G. R. Thompson; (2) Metallurgy, by Prof. A. H. Sexton; (3) Mechanical Engineering, by Dr. H. Dyer; (4) Marine Engineering and Ship-Building, by Dr. R. Caird; (5) Transport, by Mr. D. T. Sandeman; (6) Textile and Allied Industries, by Mr. Robert Macintyre; (7) Chemical Industries, by Prof. G. G. Henderson; (8) Pottery, Glass, etc., by Mr. James Fleming; (9) Municipal Enterprise and the Clyde Trust, by Mr. John S. Samuel. Principal Angus Maclean, Technical School, Paisley, is the editor of this volume.

The second handbook, on the fauna and flora of the Clyde valley, is under the general editorship of Dr. M. Laurie and Mr. G. F. Scott-Elliott. For the flora part of the handbook the main contributions are: (1) Introduction, by Mr. G. F. Scott-Elliott; (2) History of Botany, by Prof. F. O. Bower, F.R.S.; (3) Phytoplankton, by Mr. V. H. Blackman and Mr. G. Murray, F.R.S.; (4) Freshwater Algæ, by Messrs. T. Paterson, J. M. Taylor and W. W. West; (5) Diatoms, by Messrs.

T. Comber and T. Paterson; (6) Marine Algæ, by Mrs. Robertson, Messrs. E. M. Holmes and L. Batters; (7) Characeæ, by Mr. P. Ewing; (8) Lichens, by Mr. G. F. Scott-Elliott; (9) Fungi (microscopic), by Mr. D. A. Boyd; (10) Fungi (hymenœnycetas), by Mr. W. Stewart; (11) Fungi (gastromycetas), by Mr. R. B. Johnstone; (12) Hepaticæ (Liverworts), by Mr. P. Ewing; (13) Musci, by Mr. J. Murray; (14) Filices (Ferns), by Mr. W. Stewart; (15) Phanerogams, by Mr. P. Ewing.

The geological part of the handbook which is edited by Dr. Malcolm Laurie has, among others, the following contributions:—Introduction, by Mr. John Horne, F.R.S.; Metamorphic Rocks, by Mr. Peter Machair; Silurian formation, by Mr. John Horne, F.R.S.; Graptolites, by Prof. Lapworth, F.R.S.; Coals, by Mr. James Thomson; Old Red Sandstone, by Mr. J. G. Goodchild; Carboniferous Formation, by Mr. J. B. Murdoch; Plants, by Mr. R. Kidston; Corals, by Mr. James Thomson; Ostracoda, by Prof. R. Jones and Mr. T. Kirby; Brachiopoda and Gastropoda, by Mr. James Neilson; Fishes, by Dr. R. H. Traquair; Permian Rocks and Glacial Clays, by Mr. John Smith; Drift Beds and Raised Beaches, by Mr. James Steele and Mr. Thomas Scott; Rocks and Minerals, by Messrs. J. Sommerville, G. R. Thompson and J. G. Goodchild. Mr. Wm. Armour, C.E., is preparing a special geological map of the Clyde Valley for this part of the handbook.

The third handbook is to deal with (*a*) archæology of Glasgow, (*b*) educational institutions of Glasgow, and (*c*) the medical and charitable institutions of Glasgow. The contributors to part (*a*) are Mr. Robert Renwick, Town Clerk Depute of Glasgow; Mr. J. Neilson, procurator fiscal; and Mr. P. MacGregor Chalmers, who is contributing an article on the Glasgow Cathedral. Dr. J. G. Kerr is editing part (*b*), and some of the more important articles will deal with The University, by Mr. W. Innes-Addison; The Technical College, by Mr. H. F. Stockdale; The Training Colleges, by Mr. G. W. Alexander; Agricultural College, by Prof. Wright; Libraries, by Mr. Barrett; Secondary Education, by Dr. J. G. Kerr; and Primary Education, by Mr. G. W. Alexander. Part (*c*) is edited by Dr. Dickson; and contributions on the different medical institutions are given by experts such as Dr. Dalzell, Dr. Lindsay Steven, Dr. Alex. Napier, Dr. F. Fergus, Dr. Finlayson, Dr. Chalmers, and others. Prof. Magnus Maclean is the editor of this volume.

Messrs. Bartholomew are getting ready a specially prepared map. This map, along with one of the handbooks, will be presented to each member who attends the meeting, and copies of the other two handbooks may be purchased by members at a reduced price.

A large number of members from different parts of the United Kingdom have already indicated their intention of being present, and a number of foreigners have also sent in their names, including representative mathematicians, engineers, physicists, botanists and zoologists from Europe and America.

It has been agreed between the different railway companies that return tickets at single fare and a quarter will be issued, from all the principal stations in the kingdom to Glasgow, to members of the British Association, on surrender of a certificate signed by the secretary of the Association to be obtained in the beginning of September from the hon. local secretaries, 30, George Square, Glasgow. The tickets will be valid from *the day before the first meeting until the day after the last meeting.*

The following are the presidents of sections:—Section A (Mathematical and Physical Science), Major P. A. MacMahon, F.R.S.; B (Chemistry), Prof. P. Frankland, F.R.S.; C (Geology), John Horne, F.R.S.; D (Zoology), Prof. J. Cossar Ewart, F.R.S.; E (Geography), Dr. H. R. Mill; F (Economic Science and Statistics), Sir Robert Giffen, F.R.S.; G (Engineering), Col. R. E. Crompton; H (Anthropology), Prof. D. J. Cunningham, F.R.S.; I (Physiology), Prof. J. G. McKendrick, F.R.S.; K (Botany), Prof. J. B. Balfour, F.R.S.; L (Educational Science), Rt. Hon. Sir John E. Gorst, F.R.S.

It is not anticipated that there will be any difficulty in accommodating the members at Glasgow. There are a large number of comfortable hotels and the committee is preparing a list of such hotels, as well as of suitable lodgings and furnished apartments. Many Glasgow citizens have also indicated their desire to offer private hospitality to members. The Secretarium will probably be in Queen Margaret Hall, which is situated within five minutes walk of the University.

MAGNUS MACLEAN.

THE RECENT TOTAL SOLAR ECLIPSE.

THE several parties of observers who journeyed so far to see the eclipse on Saturday last were not, it appears, favoured with such good weather conditions as obtained during the previous two eclipses in India and Spain. No detailed accounts of the results are yet to hand, but from several brief telegrams in the daily Press we may gather a summary of the general observations made.

Mauritius.—The observers at the Government Royal Alfred Observatory at Mauritius appear to have had the greatest success. Even here the partial phases were only incompletely determined owing to clouds, the first contact being quite lost; the last three contacts were, however, determined fairly well. The party at this station consisted of twenty-two observers. With respect to the total eclipse itself, fifty-two photographs of the corona were obtained with the Mauritius photoheliograph, the Greenwich coronograph, the Newbegin telescope and several smaller cameras. In addition, forty-one photographs of the partial phase were taken for determining the diameter and place of the moon as a control over the ephemeris data, and eighteen photographs of the spectrum of the eclipsed sun's surroundings.

Drawings were made with a 6-inch telescope, and a kinematographic record of the eclipse also obtained.

Mr. Claxton had organised a comprehensive scheme of meteorological observations. The general report from this station is that the corona was of the expected minimum type, but fainter, more yellow and diffused than that observed in Spain last year.

Sumatra.—The expeditions to the Eastern Archipelago did not have a clear sky during totality. The instruments from Greenwich, in charge of Messrs. Dyson and Atkinson, were set up on the volcanic island of Auer Gedang, about six miles from the coast of Sumatra, on the central line of totality. Here the sky was covered with heavy rainclouds during the morning, rendering the prospect anything but hopeful. A slight improvement took place as the time of eclipse drew near, but unfortunately the sky never quite cleared. The form of the corona was observed, and the planets Mercury and Venus seen. Totality lasted 6 min. 21 sec.

The Dutch party in the same neighbourhood—at Karang Sago—were somewhat more successful, although there the sky was throughout covered with thin clouds.

Successful photographs are reported to have been obtained of the corona with different telescopes, and photographs of the spectra of the corona and chromosphere with two spectrographs. Several other branches of investigation, including photographs with the prismatic camera, measurements of polarisation of coronal light and determination of heat radiation of the corona, were unsuccessful.

The observations at the inland station of Solok were an almost total failure.

At Singapore the eclipse was very well seen, totality occurring about 12.51 p.m. An interesting series of observations of the temperature variations were made there. The reading before eclipse in full sun was 143°, which fell during totality to 81°, which was 2 degrees below the normal shade temperature.

RECENT WORK OF THE U.S. WEATHER BUREAU.[1]

THE Report of the Weather Bureau for the year ended June 30, 1899, which appeared at the end of last year, extends over two volumes. The first, which includes the usual administrative report and the climatological statistics of the United States Weather Service, is a volume of the ordinary dimensions, while the second and special volume, being part vi. of the whole report, is devoted to Prof. Bigelow's discussion of the United States' contribution to the international cloud observations. It is a bulky volume of no less than 787 quarto pages.

Glancing at the first volume, attention is turned naturally to those points in which the practice of the United States Weather Office differs from that adopted in this country, and the first point to be noticed is that from March 1899 the period covered by the night forecasts was increased to forty-eight hours, and that the extension of period has worked successfully, whereas the limit of the British forecasts is twenty-four hours. It is true that the British Isles occupy a remarkably difficult position on a weather map. They are not only at the extreme west of Europe and catch the first effects of weather changes travelling eastward, but they are in a special manner the battle-field of the elements and are vexed with all the storms that belong to so-called temperate latitudes and western shores. These adverse circumstances in a British mind should provoke more daring enterprise rather than complacency with partial successes, yet we are still without telegraphic reports from Iceland, a recognised centre of atmospheric influence, and wireless telegraphy has not yet extended westward the available area of information.

The weather service in the United States is indeed a popular one. From a table in the report it appears that the total number of addresses in the United States supplied with forecasts and special warnings reached the astonishing figures of 24,467,106. With these no British statistics can be compared.

It would require too much space to enter into details of the climatological data, which include, amongst other things, means of hourly readings at 28 stations. It should, however, be remarked that the year under review was noteworthy for the establishment of a number of stations for the storm-warning service in the West Indies at the conclusion of the war with Spain, and for the extensive system of aërial investigation by means of kites at 17 stations. This work was continued until the middle of November, 1898, by which time 1217 ascensions of 1000 feet and above had been made.

The second volume, written by Prof. F. H. Bigelow, is devoted exclusively to the cloud observations made in accordance with international agreement between May 1, 1896, and July 1, 1897. It is a very interesting and valuable contribution to the study of meteorology by observation of clouds, and the discussion is very fully carried out. The observations were of two kinds—theodolite observations at Washington, by which observers could determine the actual heights and velocities of individual clouds, and nephoscope observations at 15 stations in the United States from which velocities were estimated by the somewhat precarious method of assuming the height of the particular type of cloud observed. The theodolite observations are printed in columns arranged according to the type of cloud observed, and occupy 93 pages of the volume. Their discussion leads directly to some very interesting results as to the variation of the velocities of clouds with height.

The nephoscope observations numbered some 23,000. In order to coordinate them the whole United States area is first divided into six districts, and the position of each station for each observation with regard to a centre of high or low atmospheric pressure is identified by assigning it to one of twenty subsidiary areas within a circle of 1500 kilometres surrounding the centre of high or low pressure, as the case may be. In this way the distribution of velocity round the centres of "high" and "low" areas for each cloud level can be set out and the gradual change in distribution from the surface wind to the regular easterly march of the cirrus at about 10 kilometres height is traced.

In further discussion of the velocities at the different cloud levels, the general easterly drift at different levels is allowed for, and the residual vectors of velocity are plotted in diagrams to show the circulation components in "highs" and "lows" at the different cloud levels.

The same data enable the barometric gradients to be calculated, and the interesting results follow that the circulation phenomena are most vigorous in the middle group of cloud levels, viz. the Strato-cumulus to Alto-stratus group, and that there is no experimental evidence to show that there is an overflow of air from the upper part of a cyclonic area causing a higher pressure around it, as has been generally assumed.

The application of these results to the several districts of the United States in different typical states of weather is represented in 66 maps of the movement of the air at different levels over the United States. This completes the primary reduction of the observations. The remainder of the volume is occupied with the application of the inductive results obtained. First a section is devoted to the diurnal variation of the barometer. The diurnal variation of winds (taken from European stations) and of cloud motions at the alto cumulus, cirro cumulus and cirrus levels, taken from the cloud observations, is compared with the diurnal variation of magnetic force as part of a discussion of a possible relation between diurnal variation of barometric pressure and magnetic force. Without expressing an opinion upon Prof. Bigelow's own views, which have given rise to some controversy, it may be said that this discussion is very suggestive in view of the ideas which have recently been developed from Prof. Thomson's suggestion of "bodies smaller than atoms," Arrhenius and others, of the possible reception of particles from the sun carrying electrical charges which can move with the upper atmosphere.

Prof. Bigelow next deals with the general theory of atmospheric circulation in relation to the light thrown upon the subject by the cloud observations. He commences the discussion by a general review of his mathematico-meteorological troops. All the numerical, thermodynamical and hydrodynamical formulæ available for meteorological warfare are paraded for inspection by the reader, and they are clothed in a new uniform on account of the need for a standard system of notation for meteorology. The uniform does not always quite fit. "Pounds $\times$ (foot)^2" seems to require some sort of inversion before it can appropriately clothe pressure. But that is a small matter. The array of formulæ is very imposing, not to say repellent, and this part of meteorology needs a uniform that is less oppressive for the civilian meteorologist. But Prof. Bigelow's investigation moves generally upon sound lines. His criticism of Ferrel's solution of the problem of the local cyclone is sound, and his diagram (chart 69) representing the alternation of high and low areas as resulting from the play of pressure due to the action of two opposing streams of air is a very useful representa-

[1] United States Department of Agriculture. Report of the Chief of the Weather Bureau, 1898–9.

tion of the origin of the conspicuous barometric changes which are characteristic of middle latitudes.

The general scheme of Prof. Bigelow's contribution is to identify and describe the actual motion of the air. There is no doubt that the identification of the stream lines in the atmosphere is a most important step towards a dynamical theory of atmospheric phenomena. When these relations, which are, of course, strictly kinematical, have been satisfactorily established by observation and experiment, the transition to the dynamical explanation will be more practicable than any attempt to calculate the state of motion of the air *a priori* from assumed dynamical causes and conditions. The procedure from the observation and accurate identification of the actual motion, even if it be complicated, to the forces which produce it has for precedent the solution of the problem of planetary motion, and it is most interesting to see a similar process shaping itself in the less amenable department of winds and clouds.

Further applications of the observations are contained in chapters xii. to xiv., wherein the observations of cumulus and nimbus clouds, incorporated with kite and balloon observations, are used to throw light on the successive stages of change which take place in air as it rises from the surface; and the reductions necessary for pressure and temperature to enable an observer, with the assistance of cloud observations, to draw up a weather map for the 3500 foot level or the 10,000 foot level are discussed, while in chapter xiv. the heat necessary to convert an "adiabatic atmosphere" into the atmosphere in its existing state is computed.

The latter part of the book is technical and based upon mathematical reasoning, and the style is by no means easy. The earlier part is observational, except that of course formulæ are employed for reduction of the direction and magnitude of the motion of the clouds from the observed data. The whole work is admirably illustrated by large numbers of well executed charts upon which a great deal of the discussion is based.

It is too voluminous and important a work to criticise here in detail. What is most conspicuous about it is the easy coordination and correlation of so many different lines of meteorological research to form a definite idea of the real course of atmospheric changes. It is possible, and even probable, that the generalisations have gone a little further than the extent of the observations warrant at present, but the discussions show in what an important manner the general study of meteorology is affected by cloud measurements, and it suggests ideas which are certainly capable of confirmation, or possibly contradiction, by further observations. They make the reader feel that observations of the height and motions of the clouds are a matter, not merely of statistical interest, but may lead to the solution of most important problems in the physics of the atmosphere and may throw light even on the obscure phenomena of terrestrial magnetism.

The Weather Bureau is much to be congratulated upon the production of a volume at once so practical and so scientific amongst its official publications.

A CANADIAN GEOLOGICAL EXPLORER.

SOME few weeks back it was announced in NATURE that Dr. Robert Bell, F.R.S., of Ottawa had been appointed director of the Geological Survey of Canada. It is an interesting coincidence that Mr. Charles Hallock has recently written and dedicated to the National Geographical Society of Washington, D.C., a paper dealing with his explorations. This American recognition of a Canadian geological explorer is so remarkable that we desire to call attention to it, especially as it gives an idea of the new director's life work, the extensiveness of which will astonish many. Mr. Hallock, who has been acquainted with Dr. Robert Bell for thirty years, is only able to give us a very brief review of what has been accomplished by this exceptionally able and energetic geologist, for the account is a short one, but we feel that it is of such general interest that the following few facts may be stated.

Dr. Robert Bell commenced his career at fifteen. At that age, and in the year 1857, he joined the Geological Survey under the late Sir W. E. Logan, then director, and served for three years as assistant to the principal members of the staff. Since then he has continued in the same work, but has acted as chief member of the various parties.

His surveys include portions of nearly every part of Canada. Beginning in the east, they comprise the "Gaspé Peninsula, from Percé to Rimouski and from the St. Lawrence to the Baie des Chaleurs, and thence to Quebec, the eastern townships, the Saquenay and Lake St. John Region, the north shore of the Gulf of St. Lawrence, the west coast and the interior of Newfoundland and parts of Nova Scotia and New Brunswick." Dr. Bell has coasted round the eastern, or Atlantic, the northern and the western coasts of the Labrador peninsula, and also round some of the islands lying off the the coast. He has calculated that the peninsula is 560,000 English square miles, a region greater than the combined areas of Great Britain and Ireland, France, Germany, Belgium and Holland.

In the summer of 1897 he visited Baffinland and surveyed most of its southern coast, besides exploring the interior, where there are many large lakes. It is worth mentioning here that only one of these lakes had before been seen by a white man. This great island of Baffinland is 1000 miles in length, and is only exceeded by Greenland and Australia in size.

The large island at the north end of Hudson Bay he has also explored, and has surveyed to a great extent the whole of the east coast of the Bay, from the Straits to the head of James Bay, also parts of the west coast of this vast inland sea, which was termed by him "the Mediterranean of North America."

Surveys have been made of the rivers flowing into James Bay. The Noddaway is the largest, and its great west tributary has been named the Bell River, after attention had been drawn to it by this eminent explorer. The rivers flowing into the Hudson Bay which he has surveyed comprise the Hayes, Steel and Hill, the great Nelson, with some of its tributaries, which drains the country as far as the Rocky Mountains, and the Great and Little Churchill rivers.

Coming further south we find his work comprises the Ottawa River from source to mouth, with its great tributary the Gatineau, and various neighbouring streams, the Montreal River and country north and south of it, and the country north of Lake Huron, including a great number of rivers and the mining district of Sudbury. The lake-peninsula of Ontario has been geologically examined by him, while he has surveyed the rivers on the north side of Lake Ontario, the Nipigon Lake, which is the most northern of the great lakes of the St. Lawrence, and also the rivers and their lakes and the country north of this to the Albany.

To the west of Lake Superior the wooded country to the prairies has been explored, and the international boundary line from this lake to the Lake of the Woods geologically examined by him. In 1881 he published a map of this last-named lake, the first ever made.

Still further west a track-survey of most of the shores of Lake Winnipeg was completed. Lake Manitoba was explored, and, further west still, the Assinniboine, Swan and Qu'Appelle Rivers and extensive portions of the North and South Saskatchewan River. A good track-survey has, further, been made of Lac la Biche and its river as far as the Athabasca River, and also of that river itself as far north as the Athabasca Lake.

On the steamship expeditions sent out by the Canadian Government to Hudson Strait and Bay, Dr. Bell not only acted as geologist and naturalist, but on the *Neptune* and *Alert* expeditions as medical officer as well.

The above is only a brief outline of the places Dr. Bell has visited and the work he has done, for no mention has been made of the time he has spent at the Great Slave Lake. This lake is 300 miles long and is a distance of 3000 miles from Ottawa, so no small journey! For the past few years, however, it has been possible to go a great part of the way by train and steamer. Here attention may be drawn to the fact that the work on the prairies and plains was accomplished before any treaties had been made with the Indians, and before the organisation of the mounted police. In those days, that part of the country was scarcely, if at all, settled, except further north, where it was practically only known to the Hudson's Bay Company's people. The buffalo was very plentiful then, and it may be surmised that the adventures of Dr. Bell were many and exciting. Taking into account all the discomfort from exposure and fatigue, the want of food, and the usual hardships connected with exploring, we may safely say that in the forty-four years of Dr. Bell's annual expeditions, he has had more adventures, more experiences of every description, and seen more of the fauna and flora of North America than any other white man living, besides having been brought into close contact with the real wild Indians, the Eskimos and the Hudson's Bay Company's people, and thus getting a thorough insight into their manners and customs.

During this time not only has he made geological, geographical and topographical surveys, but has collected a great quantity of zoological and botanical specimens, taken many photographs of these far-away parts, and made observations in a great many varied directions, greatly interesting himself in the folk-lore of the Indian tribes and the Eskimos. Dr. Bell has been called by Mr. George Johnson, the official Dominion Statistician, "the place-name father of Canada," for as his work has been so much in unknown parts he has had to give a great number of names.

In spite of the exposure and hardships he has had to experience, Dr. Bell is in perfect health and as keen and untiring about work as ever. He attributes his health to the care he has always taken of himself when camping out, always endeavouring to have a dry comfortable bed of brush or some substitute every night, trying to be as short a time as possible in wet clothes and missing as few meals as he could. It has been his habit to "live off the country and to go light," therefore he never carried any camp equipments. His food was of the simplest, being the same as that of the voyageur, with fish and game when it was to be had and with no alcoholic drinks.

Dr. Bell is of a very quiet and retiring disposition and has kept himself so much in the background that few know of the vast extent of his work. He has been the means of immense areas being mapped and divided into territories and provinces, and when we try to realise the greatness of Canada, the sizes of the rivers, lakes and plains which have been surveyed by him, the extent of land which this one man has journeyed over, we are amazed at the greatness of the work accomplished. He has published about 190 reports on various scientific subjects, but, except for short accounts like that written by Mr. Hallock, no record has been published of all his explorations, for, although often asked, Dr. Bell has never given a detailed account of his travels or attempted to extend and publish his own notes, probably owing to pressure of work and his natural reticence.

We are very grateful to Mr. Hallock for giving us an insight into what Dr. Bell has done, and wish Dr. Bell much success in his position as director of the Canadian Geological Survey.

SIR COURTENAY BOYLE, K.C.B.

BY the death of Sir Courtenay Boyle, K.C.B., which took place very suddenly on Sunday last, the country has lost a distinguished public servant and science a very warm friend and powerful supporter.

He was born in 1845, and educated at Charterhouse and Christ Church. At Oxford he became a noted cricketer, playing for the University from 1865 to 1867. In 1868 he began his official life as private secretary to Lord Spencer, then Viceroy of Ireland, an office which he held a second time from 1868–1873. After serving for twelve years as a Local Government Board inspector, in 1886 he entered the Board of Trade as assistant secretary in the Railway Department, in succession to Sir H. Calcraft, who had become permanent secretary to the Board. In 1893, when Sir H. Calcraft retired, Sir Courtenay Boyle, who a year previously had been made K.C.B., succeeded him as permanent secretary. For the past fifteen years he was intimately connected with legislation of the most important character. As assistant secretary he was responsible, along with Lord Balfour, for revising the rates and charges of the railway companies of the United Kingdom. The consolidation of the statutes relating to merchant shipping was his work, and he had much to do with the Conciliation Act of 1896.

But it was in connection with legislation to regulate the supply of electricity for light and power that he was first brought closely into relation with physical science. The position of the electric industries has changed enormously since 1886; earlier legislation had, in many respects, been hostile to their growth. Sir Courtenay's efforts were all in favour of progress, and even those who think that in some respects the progress might have been greater will admit that the difficulties to be overcome were considerable, and that the permanent secretary was always ready to give any reasonable suggestion a fair and courteous consideration. Those who in 1890-91 served with him on the committee which formulated the legal definitions of the ohm, the ampere and the volt, can testify to his care and skill; he was excellent in the chair, possibly in consequence of the fact that he made no claim to be considered an expert on the subject under discussion, but brought a trained business intellect to bear on the problem of putting into a practical form the results of scientific inquiries.

Nor were his sympathies confined to the applications of science. In the recent somewhat acute controversies respecting the magnetic observatories and electric traction, he made it clear to all that he appreciated the importance of a scientific investigation which for the present does not promise direct practical applications; and the satisfactory solution of the difficulty is due in great measure to his tact and patience.

His connection with the National Physical Laboratory was most close and intimate. He was a member of Lord Rayleigh's Committee, and took part in the discussions which led up to the foundation of the Laboratory. As permanent secretary of the Board of Trade he was an *ex-officio* member of the General Board and Executive Committee; he also served on the Finance Committee and various subcommittees, and at all of these he was a most regular and useful attendant. In Lord Rayleigh's absence he usually acted as chairman, and in that position showed a very thorough grasp of the details of the work.

In the difficult discussions which arose as to the site of the Laboratory, his counsel and support were of the highest value; he gave his time freely to the work he had undertaken, and was always ready to discuss fully with the officers of the Royal Society, or the director, the proper course to follow.

He had formed high hopes of the position which the

Laboratory might take and of its future progress, and he had it in his power greatly to help the realisation of those hopes. His death is a serious blow to the new institution—a blow the consequences of which can with difficulty be repaired. R. T. G.

THE NATIONAL ANTARCTIC EXPEDITION.

WE print below a letter which Prof. Poulton has addressed to the Fellows of the Royal Society in regard to the Antarctic expedition. In it he gives a history of the circumstances which have caused Prof. J. W. Gregory to resign the leadership of the scientific staff. The reason for this, to follow the Professor's words, is that since he left England in February changes have been made in his position in regard to the naval commander of the expedition which deprived him of any guarantee that the scientific work would not be subordinated to naval adventure, "an object admirable in itself, but not the one for which I understood this expedition to be organised." The history of the negotiations before and since the beginning of the present year—the date of the letter in which these words occur—show that when Prof. Gregory accepted the leadership of the scientific work (late in 1899), much stress had been laid on the scientific aspect of the expedition, and that the alterations made since the beginning of the present year have increased the authority of the naval commander.

At a special meeting of the Royal Society in February 1898, when the advantages of an Antarctic expedition were fully discussed, Sir John Murray, in an admirable summary of matters requiring further study, enumerated not only the depth, the deposits and the biology of the South Polar Ocean, but also the meteorology, magnetism, geology, and ice-sheet of the region; and laid special stress on the importance of landing a party to remain over at least one winter in order to study the latter points. Dr. Neumayer, Sir Joseph Hooker, Sir A. Geikie and the Duke of Argyll all enlarged on the importance of one or more of the second group. The same were mentioned by members of the deputation, which Mr. Balfour received in June 1899, and in his reply he acknowledged their importance. It is, therefore, not surprising that Prof. Gregory expected the leader of the scientific staff to be allowed a very free hand, and it certainly seems that the negotiations, described by Prof. Poulton, have tended to deprive him of initiative and to place him more completely under the authority of the naval commander. Yet this expedition will afford a great opportunity not only for geographical discovery, but also for increasing scientific knowledge; and for some most important things in the latter a prolonged stay on land is absolutely necessary. Chief among these, in addition to magnetic work, are the following:—The Antarctic land is covered by an ice-sheet greater than that of Greenland, and certainly not less than even the one which some glacialists assert to have formerly existed in Northern Europe. In that land also, as in no other place, we have a chance of obtaining the key to some curious problems in the zoology and botany, past and present, of other continental masses in the southern hemisphere. For both these problems a prolonged residence is required, and an expert who, like Prof. Gregory, is as familiar with ice and its work as he is with palæontological questions.

We may hope then that those representatives of science on the Joint Antarctic Committee whom Prof. Poulton accuses will be able to demonstrate that he is wrong and Prof. Gregory needlessly apprehensive, that Commander Scott possesses such experience in Polar exploration and has such familiarity with the branches of science which we have mentioned as to warrant a man of Prof. Gregory's age and standing in placing himself absolutely under his orders, and that the *Discovery* is a King's ship in so full and real a sense that such entire subjection, even to signing articles, is imperative. Until their explanation is before us we cannot be expected to express a final opinion on the merits of the dispute, and this we shall no doubt obtain very shortly; for those whom Prof. Poulton has accused of running the risk of subordinating scientific investigation to geographical discovery can hardly afford to let judgment go by default.

To the Fellows of the Royal Society.

THE resignation of the man who is, before all others, fitted to be the Scientific Leader of the National Antarctic Expedition will lead the Fellows of the Society to expect some statement of the causes which have produced a result so disastrous to the interests of science. The following statement gives an account of the efforts which have been made to prevent the injury which has occurred.

In the autumn of 1899 Captain Tizard, F.R.S., and I were appointed as the representatives of the Council of the Royal Society on an Antarctic Executive Committee of four, Sir Clements Markham (Chairman) and Sir R. Vesey Hamilton being the representatives of the Royal Geographical Society's Council. Our functions were defined under various heads in a printed form previously agreed upon. No. 2 instructed us to submit a programme of the Expedition for approval to the Joint Antarctic Committee (consisting of sixteen representatives of each Council), "such a programme to include (*a*) A general plan of the operations of the Expedition, including instructions to the Commander, so far as this can be laid down beforehand. (*b*) The composition of the executive and scientific staff to be employed, the duties, preparation and accommodation for, and pay of, the several members." No. 4 instructed us "To make the appointments of the several members of the executive and scientific staff, subject to the final approval of the Joint Committee." The word "civilian" was nowhere employed. The four members of the Executive Committee were placed on the Joint Committee and all Sub-Committees.

Before the first meeting of the Executive Committee Captain Tizard and I were seen by Prof. Rücker, who informed us that one of the first points which the Council of the Royal Society desired us to raise was the relation in power and status between the Commander and the Scientific Leader. In the German Expedition, which was to start about the same time, the Scientific Director had absolute power, and we were asked to consider the possibility of such an arrangement in the English Expedition.

At one of our first meetings, I think the very first, I raised this question and supported the German arrangement. The other three members, who were all naval experts, convinced me that English law required the Captain to be supreme in all questions relating to the safety of his ship and crew. Since that time I have never disputed this point, but always maintained that the scientific chief should be head of the scientific work of all kinds, including the geographical, and that the captain should be instructed to carry out his wishes so far as they were consistent with the safety of ship and crew.

We then considered the appointment of Scientific Leader and decided to nominate Prof. J. W. Gregory, then of the British Museum of Natural History. In suggesting his name to my colleagues I was influenced by his proved success in organisation and in the management of men in a most difficult expedition (British East Africa in 1893), by the wide grasp of science which enabled him to bring back valuable observations and collections in so many departments. His ice experience in Spitzbergen and Alpine regions was also of the highest importance, together with the fact that his chief subject was Geology, a science which pursued in the Antarctic Continent would almost certainly yield results of especial significance. In addition to all these qualifications Prof. Gregory's wide and varied knowledge of the earth rendered his opinion as to the lines of work which would be most likely to lead to marked success extremely valuable in such an Expedition. No one was more competent to state the probable structure of the Antarctic Continent and its relation to that of the earth. This opinion of Prof. Gregory's qualifications for the position of scientific leader of an Antarctic expedition is I know widely held among British scientific men. In their wide combination and united as they are to tried capacity as a leader they are unique, and an expedition with Prof. Gregory for its scientific chief, with as free a hand as English law would permit, was bound to yield great results.

The Committee deputed me to ask Prof. Gregory if he would consent to be nominated. In doing so I carefully explained that he could not have the full powers of the German scientific leader. He consented to consider the offer favourably, but wished for a more definite statement of his position and powers, and for a programme of the Expedition. Shortly after this he was appointed Professor of Geology at Melbourne, and left England. On the voyage he wrote a long letter to the Executive Committee (dated January 19, 1900), which he posted to me at Port Said. In it he said, "I have heard so many rumours as to what is wanted, that I cannot be sure whether I correctly understand the views and wishes of the Executive Committee: I therefore write mainly for the sake of correction, so that I may avoid any misstatements in communicating with the Council of Melbourne University, when the proposal from the Committee reaches me." The plan drafted by Prof. Gregory in this letter included the provision of a landing party with house, observing huts, dog-stable, &c., and he argued that its organisation should be placed "in the hands of the scientific staff," but that, under any circumstances, the Scientific Leader should have the opportunity of controlling a small independent party on land. This letter was read by all the members of the Executive Committee, and, on June 15, at the close of the meeting, the Secretary despatched a cable to Prof. Gregory containing the information "Your letter of January 19 has been received and approved." As soon as Prof. Gregory received this he sent a decoded copy to Sir Clements Markham, who did not correct it. Indeed, at this period Sir Clements Markham frequently expressed opinions which implied that he contemplated the establishment of a landing party independent of the ship. Prof. Gregory applied for and received from the Council of Melbourne University permission to take the appointment on the lines of his letter of January 19.

Prof. Gregory's name was very warmly received by the Joint Committee and he was appointed Scientific Head on February 14, 1900: the words "Formally appointed, wire when fully able to decide," being cabled to him a few days later by Sir Clements Markham.

Lieutenant Robert F. Scott, Torpedo Lieutenant of H.M.S. *Majestic*, was appointed Commander of the Expedition by the Joint Committee on May 25, 1900.

In June 1900 my attention was called to a statement in the Press describing Prof. Gregory as "Head of the Civilian Scientific Staff." Feeling confident that the word "civilian" was not employed in the resolution accepted by the Joint Committee I wrote to Sir Clements Markham on the subject. In his absence the Secretary replied, "The words 'Head of the Civilian Scientific Staff' are the exact words of the resolution passed by the Joint Committee appointing Prof. Gregory, and I know Sir Clements himself was very anxious to have the word 'civilian' in, so that no difficulty might arise between Prof. Gregory and the Commander of the Expedition, since the Civilians would not be the only scientific men on board." The word "civilian" does certainly occur in the minutes of the meeting. On the other hand, Sir Clements Markham was not present on that occasion (February 14, 1900); the word "civilian" did not occur in the instructions issued to the Executive Committee, and was not used in my letter to Sir Clements (February 15) describing the result of the meeting and asking him to cable. The words I used, "leader of the Scientific Staff," were not commented upon in his reply (February 16), stating that the cable should be sent. The word "civilian" was not used by Dr. W. T. Blanford writing to convey the unanimous recommendation of the Geological Sub Committee that Prof. Gregory should be "chief of the Scientific Staff of the Expedition." Prof. Herdman, who seconded the resolution on February 14, and I who proposed it, both remember the words "Scientific Leader of the Expedition." I have not been able to recover a copy of the notice convening the meeting, in which the agenda were put down. It would, however, have been unreasonable for the Joint Committee to have accepted the word "civilian" when it had no information before it which justified the expectation that naval officers would be lent by the Admiralty.

At the meeting of the British Association at Bradford I explained the situation to Prof. Rücker, who agreed with me that it was full of danger, on account of the reasons alleged for the use of the word "civilian," viz. in order to discriminate between the science under Prof. Gregory and that under the Commander. He agreed with me that the coordination of all the science of the Expedition ought to be in the hands of the scientific chief who had been selected because his reputation was a guarantee that all interests would be properly looked after. Sir Michael Foster, to whom I mentioned the matter at a later date, quite agreed with this opinion, but was unwilling to contest the use of the term "civilian." Furthermore, when I raised the question at a meeting of the Representatives of the Royal Society on the Joint Committee, it appeared that the term was actually preferred by certain influential naval authorities who were present, so that it was impossible to resist it without dividing those who desired to give Prof. Gregory such a measure of freedom of action as he was prepared to accept.

At the meeting (November 20, 1900) of the Joint Committee following the conversations with Prof. Rücker and Sir Michael Foster, a Report from the Executive Committee and Submission and Estimate from Captain Scott were read and received, with certain modifications. I indicated to the Secretaries of the Royal Society, who were sitting opposite to me, that this was a favourable opportunity to raise the question of the powers of the Scientific Director over the whole of the science of the Expedition. They were, however, unwilling to do so, hoping, I believe, that all difficulties would be smoothed away by personal negotiations between Captain Scott and Prof. Gregory, who was expected home in a fortnight.

For nearly two months these negotiations proceeded between Prof. Gregory on the one side and Captain Scott and Sir Clements Markham on the other, and between Sir Clements Markham and me.

The principles held were irreconcilable, and it only remained to appeal to the Joint Committee for a decision.

On January 9, 1901, Prof. Gregory wrote to Prof. Rücker, explaining the failure of the negotiations, and on January 28 he addressed a letter to the Royal Society's Representatives on the Joint Committee, from which I select the following paragraphs:—

"I landed at Liverpool on December 5, and went straight to Dundee to meet Captain Scott, and showed him a copy of my letter of January 19 [1900]. As he returned it to me next day without comment I believed that he understood and accepted the general conditions therein stated. On January 7, in order to settle the exact terms of our mutual relations, I submitted to Captain Scott a draft of the instructions I expected to receive from the Joint Committee, and which I had previously shown to Prof. Poulton. To my surprise Sir Clements Markham and Captain Scott expressed disapproval of these instructions, practically on the ground that there could be only one leader of the Expedition, and that that leader must be Captain Scott.

"My colleagues and myself were characterised as civilian scientific experts, accompanying the expedition to undertake investigations in those branches of science with which the ship's officers were unfamiliar, and it was proposed, that to maintain Captain Scott's complete control, all the scientific men should be required to sign articles.

"According to this theory the position of the scientific staff is accessory and subordinate. The contentions of Sir Clements Markham and Captain Scott would completely alter the position which I was invited to take and which alone I am prepared to accept. Were I to accompany the expedition on those terms there would be no guarantee to prevent the scientific work from being subordinated to naval adventure, an object admirable in itself, but not the one for which I understood this expedition to be organised."

The Executive Committee met on January 30 and drafted instructions on lines approved by Sir Clements Markham. They were opposed by my colleague Captain Tizard, but in my absence through illness were passed by two votes to one.

A few days later the draft instructions were considered by the Royal Society's Representatives, who appointed Sir Joseph Hooker, Sir William Wharton and Sir Archibald Geikie to suggest amendments. They carefully considered the draft and suggested several alterations, the most important of these being the instructions to the commander, (1) not to winter in the ice, (2) to establish between two named points on the coast a landing party with three years' stores, under the control of Prof. Gregory.

The Royal Society's Representatives again met and unanimously approved these amendments, which were submitted together with the draft instructions to the meeting of the Joint Committee on February 8. The Representatives of the Royal Geographical Society objected that they had not had the same opportunity of considering the instructions at a separate meeting, and that the amendments were sprung upon them. The meeting was accordingly adjourned until February 12, the very day before Prof. Gregory sailed. During the prolonged discussion which took place the authorities on magnetism were unanimous in affirming that a station on land was essential in order to obtain the full value of the observations made on the ship. . . .

Sir Clements Markham threatened that the Council of the R.G.S. would not accept the amended instructions, whereupon Sir Michael Foster drew attention to the letter which Sir Clements had written at the time when the Joint Committee was proposed.

The amendments were finally approved by 16 votes to 6, and Sir Archibald Geikie and I were deputed to explain to Prof. Gregory, who was in attendance, that he was to be landed in control of a small party, if a safe and suitable place could be found, and to ask if he would accept these conditions. We reported his consent to the meeting, which was then adjourned for the consideration of other details.

Two of the Representatives of the R.G.S., Sir Anthony Hoskins and Sir Vesey Hamilton, resigned shortly afterwards, explaining that they could not agree with the action of the Committee. The R.G.S. had however the right, which it subsequently exercised, of appointing new members.

At the adjourned meeting, on February 19, the question of the ship wintering was discussed at length. Those who had practical experience of the Antarctic urged us strongly not to take the responsibility of permitting the ship to winter in the ice. Sir Joseph Hooker's statement of the danger was especially impressive, and the meeting decided in accordance with his opinion.

At the same meeting Major L. Darwin proposed to modify the conditions accepted by Prof. Gregory, by adding to them the additional consideration that he should only be landed if the time of the ship should not be too greatly diverted from geographical exploration. I protested strongly against any modification at this stage. Sir Michael Foster opposed me, and, after the close of the meeting, there was a somewhat sharp though friendly expression of conflicting opinions, he maintaining that there should be "give and take," I that we were already pledged to Prof. Gregory, that the arrangement was as it stood a compromise—the minimum Prof. Gregory would accept—by no means the one which scientific men, not belonging to the Navy, would have preferred.

At that meeting Major Darwin did not succeed, but his suggestion in somewhat different words was again brought forward at the next meeting on March 5. Just before the meeting Sir Archibald Geikie told me that he intended to support the proposed changes "in the interests of peace," and that Mr. Teall, and Mr. George Murray, Prof. Gregory's representative, also approved them. Resistance was hopeless; I could only protest against any alteration of the conditions offered and accepted, requesting that my name and the names of those who agreed with me (Mr. J. Y. Buchanan and Captain Tizard) should be recorded.

I wrote to Prof. Gregory a full account of what had happened, carefully explaining that his representative and many of his friends supported the changes, that I had confidence that the proposal was made to enable the Geographical Society to accept the instructions and that it was not intended to prevent and I believed would not prevent his being landed.

In spite of the incorporation of Major Darwin's changes the R.G.S. Council refused to accept the instructions, but addressed a letter signed by their President, dated March 18, to the members of the Joint Committee stating that they were compelled, "as trustees for the money subscribed through their Society and for the funds voted by their Society, to regard the above scientific objects [viz. those to be carried out by a landing party] as subsidiary to the two primary objects of the Expedition—namely, exploration and magnetic observations." In view of the unanimous witness of all experts that the landing party was *essential* for full success in the magnetic work this statement is sufficiently remarkable.

The letter went on to inform us that the President, Sir Leopold McClintock, and Sir George Goldie had interviewed the officers of the Royal Society and had reported to the R.G.S. Council which now suggested that the Joint Committee should recommend a small Committee of six, three to be appointed by each Council, to deal finally with the Instructions. The Council of the R.G.S. agreed to accept the decision of this Committee provided the Council of the Royal Society agreed to do the same.

It has been stated in various directions that the Geographical Society produced new evidence (based upon the experience of Borchgrevink and the intentions of the German leader) which had not been laid before the Joint Committee, and thus induced the officers of the Royal Society to agree to a new Committee. To this it may be replied that these sources of information had been open to the Joint Committe, and that, if anything new had arisen, it was reasonable to refer it to the old Committee rather than to a new one appointed *ad hoc*. Furthermore, the letter of the Royal Geographical Society referred to above clearly indicated that the real intention was to escape from the conditions proposed to and accepted by the scientific leader.

The Joint Committee met on April 26, and was addressed in favour of the course proposed by the R.G.S. Council by Sir George Goldie. Nothing was said which could diminish the conviction that the R.G.S. Council and that of the R.S. in weakly consenting to nominate a fresh Committee had struck a disastrous blow at all future cooperation between scientific bodies in this country.

What reply could the Officers make if they were asked to advise the Council of the Royal Society to cooperate with that of the Royal Geographical Society on any future occasion?

I felt justified in asking what guarantee was there that the Council of the Royal Geographical Society would accept the finding of the Committee of six, when it had refused to accept that of a Committee which included all the officers and almost every expert in Arctic and Antarctic Exploration from both Societies. In reply Sir Michael Foster, in spite of the promise of firmness held out by his attitude on February 12, when Sir Clements Markham threatened that his Council would repudiate the finding of the Joint Committee, maintained that they had only acted within their rights, and that the Royal Society Council claimed the right to do the same if it had not agreed with the decision.

At this point it will be convenient to give a list of the Representatives of the Royal Society on the Joint Antarctic Committee, the Representatives of the Royal Geographical Society being equally significant in relation to the Council of their own Society. They are the President, the Treasurer, the Senior Secretary, the Junior Secretary, Mr. A. Buchan, Mr. J. Y. Buchanan, Captain Creak, Sir J. Evans, Sir A. Geikie, Prof. Herdman, Sir J. D. Hooker, Prof. Poulton, Mr. P. L. Sclater, Mr. J. J. H. Teall, Captain Tizard, and Admiral Sir W. J. L. Wharton.

If the reports of Joint Committees of such magnitude and weight are to be thrown over with the approval of the Councils of both Societies because a majority of one Council does not agree with the conclusions, men will rightly hesitate before consenting to devote an immense amount of time and trouble to the work of the Society, and the efficiency of the Royal Society will be greatly diminished.

The considerations set forth above indicate the future injuries which are likely to be inflicted on our Society by this surrender. At the meeting on April 26 I was more concerned with the immediate and pressing injury, and therefore urged that the Royal Society was a trustee for the interests of science and that we had pledged ourselves to secure certain powers to the Scientific Director, that it was better the Expedition should not start (a contingency contemplated as possible by Sir George Goldie, but not a serious danger, I believe, even though the Royal Society had stood firm and appealed to the Government, not on the subject-matter in dispute, but on the refusal of the Royal Geographical Society to work with the recognised methods of cooperation) than that the Royal Society should betray its trust, that the Fellows of the Society would not support the Officers in thus yielding to the Royal Geographical Society, and that I should feel bound to explain my position to the Society. Sir Archibald Geikie and Mr. J. Y. Buchanan also strongly objected to the surrender, which was then confirmed by a large majority of those present.

We were told by Sir George Goldie that the three Representatives of the Royal Geographical Society on the new Committee would be Sir Leopold McClintock, Mr. Mackenzie, and Sir George himself; by Sir Michael Foster that the Royal Society Council would appoint three non-experts, viz. Lord Lister, Lord Lindley and the Treasurer, who could pronounce without bias upon the whole of the evidence. My colleague, Captain Tizard, with whom I had worked with the most complete sympathy and agreement through the whole course of the negotiations, supported the formation of the new Committee because of Sir Michael's assurance that all evidence would be sifted and because of his faith in the validity of the evidence he had to give. Others probably voted in the affirmative for the same reason.

Without asking for evidence from Sir Joseph Hooker, Sir W. Wharton, Sir George Nares, Sir A. Geikie, Captain Creak, Captain Tizard, or Mr. Buchanan, the new Committee proceeded to cable to Melbourne the modifications which have led Prof. Gregory to resign.

In bringing a condensed account of the negotiations before the Fellows of the Royal Society I desire to call attention to certain special difficulties which the Society has had to encounter in the struggle.

(1) The fact that nearly the whole of the money voluntarily subscribed was obtained through members of the Geographical Society and from its funds.

(2) The fact that Sir Clements Markham, President of the Royal Geographical Society, a man of remarkable energy, resource and resolution, was the chief antagonist of the amendments passed by the Joint Committee.

(3) The fact that the Junior Secretary and Sir John Evans were absent from England during the most critical period.

(4) Prof. Gregory's appointment to the Chair at Melbourne, involving his absence from England during a large part of the negotiations.

Making all allowance for these difficulties, I believe that the majority of the Fellows will consider that the claims of the Scientific Chief in an Expedition undertaken to do scientific work have not received from the Royal Society that unflinching, undivided and resolute support which they would have expected and desired. EDWARD B. POULTON.

Oxford, May 15.

NOTES.

We understand that the council of the Society of Arts has awarded the Albert Medal for the present year to the King, and that His Majesty has graciously consented to accept the award. The grounds of the award are principally the services the King has rendered to the Society, and through it to the arts, manufactures and commerce of the country, by acting as its president for thirty-eight years; but reference is also made to the active interest he has long taken in international exhibitions and the actual work which he did as president of the British Commission for several foreign exhibitions, and also as president of the series of exhibitions held at South Kensington, the last of which was the Indian and Colonial Exhibition.

Dr. Laveran, the French surgeon who first investigated the peculiar micro-organisms in the red blood corpuscles of malarious patients, has been elected a member of the Paris Academy of Sciences.

The Report of the Royal Commission upon the British exhibits at the Paris International Exhibition last year has been presented to the King, and some of the observations in it will have to be given serious consideration before the country is represented at any future exhibition of the same character. Indifference to progress abroad and want of combination among manufacturers are two reasons given for the comparatively poor display of British exhibits. It is pointed out that our position has changed since the earlier exhibitions; for foreign industries have made gigantic strides, and in many branches of manufacture have become formidable rivals to our own in the markets of the world. On this account the industrial interests of the country as a whole gain nothing from an exhibition unless they are represented upon equal terms with foreign industries. "We are of opinion," reports the Commission, "that the voluntary system can no longer be relied upon to secure an adequate representation of British industry, and that in any future international exhibition in which it may be decided to take part, it will be necessary to have recourse to the principle of selection, which has been largely adopted by foreign Powers. . . . The contrast between the orderly, symmetrical appearance of the foreign spaces in certain groups with the undignified collection of show cases of different sizes and design which filled the British space was little less than painful." Commenting upon the causes of this conspicuous defect, the Commission says:— "As a rule a British manufacturer will only exhibit if he can select his own goods and display them in his own way and in his own show-case. He is impatient of advice; he will not submit to dictation; he will not share his show-case with others; nor will he join with others to adopt a uniform plan of arrangement. For this reason it is exceedingly difficult to organise collective exhibits. We were strongly impressed from the beginning with the advantages which such exhibits possess. They save space, they avoid the duplication of similar objects, and, in the case of many industries, they ensure a higher level of excellence than any single firm can hope to attain. We endeavoured to persuade exhibitors to adopt the principle, but our efforts met with so little success that we had to abandon the attempt." This is another example of the want of enterprise among British manufacturers, and the narrow spirit in which our commercial affairs are managed. There can be little hope of national progress until broader views are taken of our industrial responsibilities.

This week we have the announcement of what may be safely called the most munificent gift of our time by a private individual to the cause of education in this country. Mr. Andrew Carnegie, the American millionaire, has come forward with a proposal to provide free University education to the youth, both male and female, of Scotland, and offers to place the sum of two millions of pounds in the hands of trustees who shall be charged with the duty of making payment to the Universities of Scotland of the fees of students of Scottish birth. There can be but one opinion regarding the large-heartedness which prompts so magnificent a benefaction, and the whole nation will hope that a sound result may be obtained through so noble a gift. Its terms have as yet been too baldly stated to justify critical analysis of its probable effect, but touching, as it does profoundly, the educational system of the country, the form it will ultimately take is a matter of the utmost moment. Two obvious criticisms evoked by the bare statement that has been made public may, without detracting from the generous intention of the donor, be noted. In the first place, the consequence of the gift as adumbrated must be that secondary education will, in Scotland, alone be unendowed. The gift would be a step towards the realisation of the dream, many times dreamed of old, of education free from bottom to top. This may or may not be a sound policy, but it demands discussion upon its merits and apart from the compulsion of the gift of an individual. What is in Scotland to-day will be required in England to-morrow. Secondly, the gift is no endowment of the Scottish Universities, but it may, on the contrary, be an embarrassment to them. It means the creation of some sixteen hundred bursaries, each of the value of nine pounds, in each of the Universities. This will not bring an influx of sixteen hundred students to each University, but, if Mr. Carnegie's intention be realised, we take it there will be a considerable increase in the number—sufficient, indeed, to swamp the existing equipment for teaching, for the strengthening of which their fees may be inadequate. Whilst it is earnestly to be wished that this large sum of money may be secured to the cause of education, it is to be hoped that those with whom Mr. Carnegie may take counsel will use their influence to harmonise his evident intention to benefit the masses with the real educational needs of the country and with the work of the Universities.

THE anniversary meeting of the Royal Geographical Society was held on Monday, when the president, Sir Clements Markham, K.C.B., distributed the medals and prizes for the encouragement of geographical science and discovery. The founder's medal was awarded to the Duke of the Abruzzi for his expedition to Mount St. Elias in North-West America, and towards the North Pole by the Franz Josef Land route. The patron's medal was awarded to Dr. A. Donaldson Smith, for his African explorations and surveys. Other awards were the Murchison award for 1901 to Mr. John Coles, for his services to geography and to the Society as map curator and instructor during a period of twenty-two years. The Gill memorial for 1901 to Captain Cagni, for his journey over the frozen ocean to latitude 86° 33′ N. The Back grant for 1901 to Sub-Lieutenant W. Colbeck, R.N.R., for the survey work which he did in Victoria Land, and during the voyage of the *Southern Cross*. The Cuthbert Peek grant for 1901 to Mr. L. C. Bernacchi, for his series of scientific observations taken in Victoria Land and the Ross Sea. After the presentation of the medals the president delivered an address, in the course of which he referred to the recent international conference in Christiania for the exploration of the ocean, and to the equipment and the arrangements connected with the National Antarctic Expedition. After mentioning the matters dealt with in another column and sketching the programme of work to be done by the expedition, the president said it was necessary that there should be a second ship ready to proceed south in November, 1902, in the possible contingency of any accident or of the detention of the *Discovery*. It was also very desirable that there should be sufficient funds for a third year. But the first of these objects was essential. A whaler might be bought or hired, and she would have to be manned and provisioned. The cost would be about 15,000*l*., towards which amount 5000*l*. had been promised by one donor and 500*l*. by another.

The annual conversazione of the Institution of Electrical Engineers will be held at the Natural History Museum, South Kensington, on Friday, June 14.

MR. R. W. DANA has been appointed secretary to the Institution of Naval Architects, to succeed Mr. G. Holmes, who has accepted a position under Government.

AT the annual meeting of the African Trade Section of the Liverpool Chamber of Commerce held on Monday, Mr. Alfred L. Jones, the president, remarked that all West African people had lent themselves heartily to support the great effort of the Liverpool School of Tropical Medicine, which the Chamber of Commerce initiated. Mr. Chamberlain has written a letter in which he expresses pleasure "that through the generosity of a Glasgow citizen, and by the action of Major Ross, who is prepared to give his services without remuneration, the Liverpool School of Tropical Medicines has been able to arrange that Major Ross should proceed to West Africa for the purpose of endeavouring to effect the extermination of the Anopheles mosquito in a selected town. It is understood that Major Ross proposes to select a town for the experiment either in Sierra Leone or the Gold Coast, and the Governors of these colonies have been requested to afford him all the assistance in their power."

AT the Royal Institution to-day Prof. Dewar will deliver the first of a course of three lectures on "The Chemistry of Carbon." On Tuesday, May 28, Prof. William Knight will begin a course of two lectures on "The Philosophical Undertones of Modern Poetry" (the Tyndall Lectures), and on Saturday, June 1, Prof. J. B. Farmer will deliver the first of three lectures on "The Biological Characters of Epiphytic Plants." The Friday evening discourse on May 24 will be delivered by Mr. R. T. Glazebrook, on "The Aims of the National Physical Laboratory," on May 31 by Mr. A. H. Savage Landor, on "With the Allies in China," and on June 7 by Prof. R. Meldola, on "Mimetic Insects."

THE *Times* announces the death, at St. Petersburg, of Dr. E. Bretschneider, one of the most distinguished students of Chinese history and knowledge of his time. For many years Dr. Bretschneider was physician to the Russian Legation at Peking, and took advantage of his exceptional position to devote himself to the investigation of Chinese archæology, history, language, geography, &c. One of his latest works is a "History of European Botanical Discoveries in China," and another one of the best maps of China available, both of them in English. Among other works from his pen are the following:—"On the Study and Value of Chinese Botanical Works"; "Fu-sang, or Who Discovered China"; "On the Knowledge possessed by the ancient Chinese of the Arabs and Arabian Colonies"; "Notes on Chinese Mediæval Travellers to the West"; "Archæological and Historical Researches in Peking and its Environs"; "Mediæval Researches from Eastern Asiatic Sources." Dr. Bretschneider was an honorary corresponding member of the Royal Geographical Society, as well as of many other societies.

As already announced, the sixth annual congress of the South-Eastern Union of Scientific Societies will be held at Haslemere and Hindhead on June 6–8. An address will be given by the president-elect, Mr. G. A. Boulenger, F.R.S., and a number of interesting papers are down for reading, among them being the following:—Moisture in the atmosphere, the Hon. Rollo Russell; certain aspects of post-Darwinian work in zoology, Prof. G. B. Howes, F.R.S.; seedlings, Miss E. Sargent; the teaching of nature knowledge in elementary schools, Miss A. M. Buckton and Prof. A. D. Hall; habit and discipline in their influence on organisation, Dr. Jonathan Hutchinson, F.R.S.; an eclipse trip to Portugal in 1900, Mr. G. F. Chambers; cuckoos' eggs, Mr. Oswald H. Latter; and the origin of certain weeds, Mr. S. T. Dunn.

PROF. H. H. GIGLIOLI, of the Royal Zoological Museum, Florence, informs us that on April 13 the second annual meeting of the Zoological Union of Italy concluded its work at Naples. This Union was formed at Pavia last year and in the following September it held its first general meeting at Bologna, which proved to be quite a success as to the work performed and the large attendance. It became evident that the Union, the scope of which is to collect the scattered forces of students of zoology and to prepare the way for the foundation of a zoological journal worthy of Italian science, has responded to a wish generally felt in Italy. The Union now counts amongst its members nearly all the Italian professors of zoology and anatomy and many other students of those sciences. The meeting at Naples was even more numerous than that at Bologna, and many interesting communications were read. Bologna greeted the assembled zoologists with the memories of its old masters—Aldrovandi, Malpighi, Alessandrini and others; at Naples they were *fêted* by that great centre of zoological investigations, the Zoological Station, whose steam-launch, which bears the glorious name of *Johannes Müller*, gave the visitors practical examples of pelagic trawling and dredging, as the war steamer *Ercole* bore them to Capri. Rome has been chosen for the third congress, in 1902, "when," remarks Prof. Giglioli, "we shall be proud and happy to welcome any of our foreign colleagues who should choose to honour us with their presence."

WE are indebted to the president of the International Aëronautical Committee for the following preliminary results of the balloon ascents on April 19. The number of balloons was 19, of which 6 were manned, and the countries that participated in the investigation were Austria, France, Germany and Russia. The results of the manned ascents from Berlin and Vienna were remarkably coincident: Berlin, temperature at starting, 5°·6 C., and −25°·5 at an altitude of 5500 metres; Vienna, 5°·0 at starting, and −25°·0 at 5260 metres. The greatest heights attained by the unmanned balloons were: 10,500 metres at Strassburg, temperature −54°; 11,100 m. at Trappes (near Paris), temperature −62°; 11,848 m. at Chalais-Meudon, temperature −52°·8 C. The only instance in which an inversion of temperature was recorded appears to have been at Strassburg, but the balloon, which was made of paper, burst at an altitude of 1500 metres.

A GENERALISATION of Clairant's form in the theory of differential equations of the first order, based on certain considerations given by Raffy, is contained in a note by Signor Minea Chini in the *Rendiconto* del R. Istituto Lombardo, xxxiv. 8. In this note the author examines what are the types of differential equations of the first order in x, y whose general integrals are obtainable by replacing the differential coefficient p in the original differential equation by a previously determined function, (i.) of x, C, (ii.) of x, y, C, where C is an arbitrary constant.

A SHORT note on the propagation of *Filaria immites* by the agency of mosquito bites is contributed by Signor G. Noè to the *Atti* dei Lincei, x. 8. It has now been conclusively proved that the filariæ of the blood are transmitted from one host to another by mosquitoes which act as intermediate hosts. An experiment, in which a healthy dog was made to eat hundreds of Anopheles, both from infected regions and others infected in a laboratory, without itself becoming infected, excludes the possibility of the parasites being propagated otherwise than by punctures.

THE *Transactions and Annual Report* of the Manchester Microscopical Society for 1900 bears ample testimony to the flourishing state of that institution and the keenness of its members for hard work. The address of the president, Prof. S. J. Hickson, deals with the reproduction and life-history of the Protozoa, special attention being directed to recent investigations on that group and the alteration in our views thereby rendered necessary. It is now inexact to say that the Protozoa are, as a general rule, animals of simple constitution, many of them being, to a certain extent, specialised. Among other papers, Mr. M. L. Sykes contributes an exceedingly interesting article on smallpox and vaccination, and the mode of producing glycerine cultivations of vaccine lymph, which may be commended to the best attention of anti-vaccinationists.

THE two issues (Nos. 9 and 10) of the *Biologisches Centralblatt* for May contain articles dealing with the freshwater invertebrate fauna of Lake Baikal. In No. 9 Herr W. Zygoff discusses the sabellarian annelid from the lake described by Prof. J. Nusbaum in the same journal for January 1 as the first known freshwater member of its group under the name of *Dybowscella baicalensis*. It is pointed out that a North American freshwater form, *Manayunkia speciosa*, was described long ago by Leidy, and it is urged that the one inhabiting Lake Baikal is inseparable. In the following article Prof. Nusbaum disputes this identification, alleging that while Manayunkia is hermaphrodite, in Dybowscella the sexes are distinct. No. 10 contains a general article on the fauna of the lake by Herr A. Korotneff, in which a new freshwater polyzoan is described as *Echinella placoides*.

UNDER the title of "A Theory of the Origin and Evolution of the Australian Marsupials" Mr. B. A. Bensley, in the April number of the *American Naturalist*, publishes a further account of the result of his investigations into the history of that group. Starting with the well-known fact that the group simulates most of the placental orders, the inference is drawn that its evolution or "radiation," has taken place within its present habitat. Reasons are then given for regarding the banded anteater (Myrmecobius) as a degraded type; and if this view be accepted, all the other types can be derived, both as regards their dentition and their feet, from the American opossums, the ancestors of which are regarded as the progenitors of the whole group. All the Australian marsupials thus appear to have had an arboreal ancestry; and when, in spite of the specialisation of certain forms, the primitive character of the whole group is borne in mind, it seems evident that the date of the "radiation" is comparatively recent. Hence the author is inclined to side with those who consider that marsupials first entered Australia during the Tertiary period, although he thinks their arrival was later than has previously been considered possible. As to whether their immigration was from the north or from the south he is undecided, although he states that "there is at least some justification for the view that it was from the northward," *i.e.* by way of Asia.

DURING his travels in Southern India (1816–20), with a view to the economic development of Pondicherry and other French possessions in the East, Leschenault de la Tour made a valuable collection of rocks, which are preserved in the Museum of Natural History in Paris. Some of the rocks, pyroxenic and scapolitic gneisses, were described in 1889 by Prof. A. Lacroix, but as their geological relations had not been determined, Mr. T. H. Holland, of the Geological Survey of India, has specially examined the entire collection in Paris, and has also investigated the area from which the rocks were obtained. His observations are recorded in an article on the geology of Salem, Madras Presidency (*Mem. Geol. Surv. India*, vol. xxx. part 2, 1900). The rocks which he describes are, in probable order of age, (1) fundamental biotite-gneisses; (2) schists; (3) pyroxene-granulites; and (4) younger igneous intrusions, including basic dykes, peridotites and "white elephant" rocks—masses of quartz having the characters of plutonic quartz and containing much liquid carbonic acid.

IN the May issue of the *Cambrian Natural Observer*, Mr. Arthur Mee directs attention to the state of the grave of the Rev. T. W. Webb, author of the classical "Celestial Objects for Common Telescopes," in the churchyard of Mitchel Troy, near Monmouth. There is no reference on the stone to indicate the invaluable work accomplished by Webb, and Mr. Mee suggests that some means be adopted of suitably recording the services rendered to astronomy by the deceased divine.

THE peculiar thermal properties of the alloys of nickel and steel discovered by M. C. E. Guillaume have already met with more than one application, the existence of an alloy with a practically negligible coefficient of expansion pointing to an ideal material for the construction of length standards for geodesic measurements. In the current number of the *Comptes rendus* is described a further application by M. Guillaume of this material. The secondary compensation error of a chronometer, discovered by Dent in 1833, is due to the fact that a chronometer adjusted for two fixed temperatures is not perfectly adjusted for any other temperature. In the present paper, it is shown that by the use of a suitable nickel-steel alloy it is possible to compensate perfectly the variations of elasticity of the spring with a balance of the ordinary form.

THE same number of the *Comptes rendus* contains an important communication by M. Jean Friedel to the theory of chlorophyll assimilation. It is usually held that three conditions are necessary for the assimilation of carbon—the presence of chlorophyll, the existence of living protoplasm in contact with the chlorophyll, and light rays. The results of the experiments described in the present paper would appear to show that the second condition is not essential. A glycerine extract of the leaves, filtered first through paper and then through a Chamberland porcelain filter, and containing no trace of cells or even of protoplasmic débris, shows no assimilation in either light or darkness. The leaves of the same species dried at 100° C. gave a green powder containing no living matter, an extract also showing no assimilating power in the light. But a mixture of these two extracts exposed to the light readily absorbed carbon dioxide and gave off oxygen. From these experiments the author concludes that chlorophyll assimilation is accomplished without the intervention of living matter by a diastase which utilises the energy of the sun's rays, the chlorophyll acting as a sensitiser.

THE additions to the Zoological Society's Gardens during the past week include a Red Howler (*Mycetes seniculus*) from Colombia, presented by Commander A. Jolliffe; an Arctic Fox (*Canis lagopus*) from the Arctic Regions, presented by Dr. H. A. Allbutt; a Black-faced Kangaroo (*Macropus melanops*, ♀) from Tasmania, presented by Miss Amy Mitchell; two Barred Doves (*Geopelia striata*) from India, presented by Mr. W. A. D. Harding; an Allen's Porphyrio (*Hydrornia alleni*), captured at sea, presented by Miss V. I. Nielsen; a Rook (*Corvus frugilegus*), British, presented by Mr. A. Yates; a Spider Monkey (*Ateles*, sp. inc.), a Kinkajou (*Cercoleptes caudivolvulus*), a Feline Douroucouli (*Nyctipithecus vociferans*), a Corais Snake (*Coluber corais*) from South America, a Vulpine Phalanger (*Trichosurus vulpecula*), a Short-tailed Wallaby (*Macropus brachyurus*), two Quoy's Lizards (*Lygosoma quoyi*) from Australia, an —— Ibex (*Capra*, sp. inc.) from Persia, two Simony's Lizards (*Lacerta simonyi*) from the Canaries, six Tigrine Frogs (*Rana tigrina*) from the East Indies, three Schlagintweit's Frogs (*Rana cyanophlyctis*) from Southern Asia, five —— Skinks (*Eumeces skiltonensis*), four Changeable Tree Frogs (*Hyla versicolor*) from North America, a Californian Toad (*Bufo boreas*) from California, two Hamilton's Terrapins (*Damonia hamiltoni*), four Bungoma River Turtle (*Emyda granosa*) from India, deposited; two Common Teal (*Querquedula crecca*), a Shag *Phalacrocorax graculus*), European, purchased; a Japanese Deer (*Cervus sika*, ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

NEW VARIABLE STAR 71 (1901) AURIGÆ.—Mr. Stanley Williams announces in the *Astronomische Nachrichten*, Bd. 155, No. 3708, the discovery of variability in the star B.D. +42°·1295, the position of which is

$$\left.\begin{array}{l}\text{R.A.} = 5\text{h. } 18\text{m. } 19{\cdot}5\text{s}\\ \text{Decl.} = +42^\circ\ 18'{\cdot}5\end{array}\right\}(1855{\cdot}0).$$

The magnitude variations have been measured from photographs taken with a portrait lens of 4·4 inches aperture, and the following are the elements deduced:—

Period, 0·7925d. = 19h. 1m. 12s.
Epoch max. 1901 March 3 (2415447), 13h. 0m. G.M.T.
Limits of variation, 8·75 mag. to 9·65 mag.
Max. to min., 14h. 13m.
Min. to max., 4h. 48m.
Ratio of increase to decrease = 0·34.

SPECTRUM OF ζ PUPPIS.—In *Harvard College Observatory Circular*, No. 55, Prof. E. C. Pickering gives the results of a new investigation by Mr. King of the spectrum of ζ Puppis with relation to the new lines of hydrogen found in that star some time ago. The lines occur also in δ and ε Orionis and the spectra of these stars have consequently been used in the reduction. The first line of the series corresponding to the red ordinary line has not yet been recorded, and the observed series consists of seven lines whose measured wave-lengths were 5413·6, 4542·4, 4200·7, 4026·0, 3924·0, 3860·8, 3815·7.

DEFINITIVE ORBIT OF COMET 1894 II. (GALE).—In the *Astronomical Journal* (vol. xxi. Nos. 496–7), Mr. H. A. Peck brings together all the available published observations of this comet from April to July 1894, and from their discussion computes the definitive elements referred to the mean equinox and ecliptic of 1894·0, which are the following:—

$$\begin{aligned}T &= 1894 \text{ April } 13{\cdot}406912 + 0{\cdot}0003958\nu\\ \omega &= 324^\circ\ 12'\ 22''{\cdot}52 + 1{\cdot}2046\delta\nu\\ \Omega &= 206\ \ 23\ \ 53{\cdot}04\ \ - 0{\cdot}5347\delta\nu\\ i &= \ \ 86\ \ 59\ \ 18{\cdot}19\ \ + 0{\cdot}8478\delta\nu\\ q &= 0{\cdot}9830931 + 0{\cdot}000001339\delta\nu\\ e &= 0{\cdot}9911206 + 0{\cdot}000002837\delta\nu\end{aligned}$$

$\delta\nu$ will most probably have some value between $-20''$ and $-60''$. For $\delta\nu = 40''$ the period of revolution would be 1143 years. The orbit of this comet appears to indicate peculiar relations to that of Jupiter. During the entire period of visibility, and for two or three years previous, the planet was near the orbit plane. A computation of the perturbations due to the major planets is now in progress.

THE UNIVERSITY OF LONDON.

THE presentation of prizes and degrees at the University of London on Wednesday, May 15, was the occasion of some noteworthy remarks upon the work and promise of the University. We give the Vice-Chancellor's address, together with parts of subsequent speeches.

Sir Henry Roscoe said,—"The past year has been one of loss and sorrow not only to the whole nation but also to this University. It has, however, I hope, been a year of some achievement. The death of her late Majesty, Queen Victoria, deprived us not only of our visitor but also of our foundress, and it is no small matter to have such a name to look back upon. For, although the earliest charter of the University bears date 1836, and was amongst the last of those issued by King William IV., yet no real start had been made in the work of the University previous to the accession of the Queen, and at the commencement of her reign she showed her interest by formally renewing the first charter of the University. This early interest never declined and, in 1870, when, after long delay, the University was granted by the Government a home of its own in Burlington-gardens, it was the Queen who personally opened the building on the presentation day of that year.

"The senate and graduates of the University presented a respectful address of condolence and congratulation to His Majesty, King Edward VII, on his accession, and the King in his gracious reply, which I will venture to read to you, was pleased to express his own continued interest in this University. His words were as follows:

"'I thank you for your loyal and dutiful address and for your sympathy with the grief of myself and my family for the death of my beloved mother.

"'The progress of your University, from its commencement almost at the date of her late Majesty's accession to its recent reorganisation as a teaching as well as an examining body, has been one of the most remarkable developments witnessed in a reign memorable for the spread of higher instruction among both sexes and all classes and races in my Empire.

"'You may feel assured of my hearty sympathy and good wishes and cooperation in the furtherance of your good work.'

"It will be in the recollection of many of you that, exactly a year ago to-day, it was the speaker of these words who, as Prince of Wales, sat on the right hand of this chair and spoke words of hope and good augury for the future upon our recent occupation of this newer and larger abode.

"But it is not only the death of the Queen that we have to regret. A most serious illness has, during the last few months —months of critical import for the University—made it impossible for our Chancellor to take any part in our work. He has, you will all be glad to hear, made a marvellous recovery, and he has sent me a letter to read to you from which you will see the deep interest he continues to take in all our affairs. It will be no small pleasure to him to think that, in his absence, we have as our guest his old colleague and friend, Lord Rosebery.

"It has been the lot of our Chancellor for many years past to speak with hope deferred of the creation of a great teaching University in and for the metropolis. This year, if it is not exactly in my power to say that the reconstitution and re-organisation have been completed, yet this one can say, that it will be chiefly ourselves whom we shall have to blame—I mean the teachers, the schools, and even the senate of this University—if a great centre of learning and research does not grow up in London.

"For although, ladies and gentlemen, the old work of the University will be continued in the future as it has been in the past—even, I may hope, with increased prosperity—although the examination of all candidates, no matter what their origin or their means of knowledge, will continue with that absolute fairness and impartiality upon which the University has built up so great a reputation, yet we must not deceive ourselves. The most perfect examinational system conceivable can only, to quote the words of the reply from the throne, add to the 'higher instruction' of a nation. But this is not enough. If we are to meet successfully the constant changes of thought and manner of life to which a highly organised society is increasingly liable, our Universities must not be content with giving instruction or testing attainment, however high, but must make real contribution to the knowledge which alone in some form or other will be a guarantee of the stability of that society. Unless the University of London is known as a centre from which almost daily additions to our understanding of the world of thought and matter emanate, we shall not have justified our existence.

"But, ladies and gentlemen, how is this end to be attained? Such results cannot come from a few weeks' work, or without the expenditure of much energy and money. In the first instance it should be our object to reduce to a minimum the wastage of our forces by overlapping and friction between the various elements of the University already existing. The need for concentration in preliminary medical studies is one of the most urgent of these early steps, not merely—not even chiefly—because it is a waste to have the work in these junior departments spread over London with frequently inefficient or duplicated equipment, but largely because the relief that would come to the medical schools by concentrating these studies in two or three central institutions would place at the disposal of the authorities opportunities and space badly needed for conducting research in pathology, bacteriology and the other higher branches of medical and surgical science.

"Such a concentration, as has been suggested in the case of the Medical Faculty, will doubtless lead to difficult problems which will require, and, I am sure, will receive, the whole-hearted cooperation of the various schools and teaching institutions of the University for their successful solution.

"It will not be necessary, I hope, to remind you that it will be ultimately impossible for each school of the University to fulfil within its four walls all the functions that belong to a university such as we conceive it to be at the present day. There are parts of London in which certain kinds of study can be much more profitably pursued than in others. It would be foolish, for instance, to attempt to centralise the study of ancient literature and archæology in Surrey or even in South Kensington, whereas we have materials around us here without parallel for the study of natural history, or of the history of modern art, to say nothing of pure and applied science. As opportunity arises for the better equipment of this or that branch of learning, it should be our aim to inquire in what part of London this equipment can be placed so as best to make use of facilities already existing and so as best to attract the largest possible number of good students. If this be our policy, our University will in course of years become an Imperial University in an altogether new and fuller sense, and the reputation that it will win for itself in the world of thought will bring it those more solid rewards without the aid of which its successful working will be seriously endangered.

"But without the schools of the University we can do nothing, and I venture to take this, the first, opportunity of calling upon them here—to-day—to take their share in this movement and to believe that the best hope of success for each member of the body corporate will be found in the prosperity of the whole."

Lord Rosebery said, in the course of his remarks, "In my judgment the struggle of this coming century will not be so much one of brute force as of trained intelligence. In the diplomacy of the world, in the markets of the world, in your arrangements of legislation and of government, it will be intelligence that will win. There was a time, I do not doubt, not so long ago, when the nations of the world were satisfied with a very moderate degree of instruction and intelligence. The schoolmaster, we are told, was abroad—I think it was said by Lord Brougham and probably in this University—and he has been so much abroad that no nations are satisfied with the standard of education that prevailed 25 years ago. Every nation demands a more keen and more trained and, if I may use the adjective, a more versatile intelligence than that which was adequate for the business methods of the Empire in former days. In other words, we have to meet much keener competition in every department of life. I hope, though perhaps not with much confidence, that all our educational institutions in this country are recognising that fact, or are about to, and are preparing to furbish up their somewhat antiquated methods in some cases to meet the demands of modern civilisation and modern competition. That is what this University has done, and is doing; and that is why I am so happy to be here to-day and to give my modest and unasked for benediction to these proceedings."

Sir Michael Foster held that there must be in London a University devoted, not only to the spreading of knowledge, but also to the making of knowledge.

Lord Reay said that London could offer facilities for research in every domain second to none in the civilised world. They might look forward to an increasing number of students from every part of the Empire to make use of those resources. Modern requirements were constantly growing, and they could not cope with the demands made on them without the exercise of public spirit which was so brilliant in the United States of America.

THE LANGUAGE AND ORIGIN OF THE BASQUES.

THE Basques or Euskaldunak (*i.e.* "the Men"), as they call themselves, are a most remarkable people who have long been an interesting problem to ethnologists. The most anomalous point about the Basques is their language, which is as typically agglutinative as any Asiatic or American tongue. Ripley, in his fine book "The Races of Europe," points out that the verb habitually includes all pronouns, adverbs and other allied parts of speech; as an example of the appalling complexity possible as a result, Bladé gives fifty forms in the third person singular of the present indicative of the regular verb "to give" alone. Another often quoted example of the effect of such agglutination occurs in a reputed Basque word meaning "the lower field of the high hill of Azpicuelta," which runs,

Azpilcuelagaraycosaroyarenberecolarrea.

No wonder that the French peasants state that the devil studied the Basque language for seven years and learned only two words. Like many other undeveloped languages, the principle of abstraction or generalisation is but slightly developed; for example, as there is no general word for "sister" the Basques have to say "sister of the man" or "sister of the woman," &c. Owing to their isolation on both flanks of the Pyrenees, many primitive institutions persist among the Basques. In some places the eldest daughter takes precedence over all the sons in inheritance, which may be a relic of a former matriarchal family; communal ownership within the family is frequently practised. The remarkable custom now known as the couvade, in which the father takes to his bed on the birth of a child, was attributed to these people by Strabo, and it is believed by some not to have completely died out at the present day, though there is great difficulty in proving its existence, as G. Buschan points out in *Globus* (Bd. lxxix. p. 117). H. Schuchardt has recently (*Globus*, Bd. lxxix. p. 208) expressed his wonder that this statement has again been dragged from the realm of fable. The same writer makes some remarks on misapprehensions respecting the Basque language.

Many wild theories have been promulgated as to the origin of the Basques, one of the most absurd being an attempt to relate them with a certain tribe in Central America. Several scholars have sought to affiliate the people with Lapps and Finns, and they have been supposed to be related to the ancient Egyptians, the ancient Phœnicians, the extinct Etruscans and to the Picts. The Basque language appears to be absolutely without connection with any of the so-called Turanian (Ural-Altaic) languages, since, as Keane shows in his "Man Past and Present" (p. 460), there is no longer any doubt as to the relationship of the Basque with the Berber language.

The anthropometrical evidence has given rise to much controversy. The French Basques have an average cephalic index (on the living) of 83, while the Spanish Basques average 78, according to Collignon, and 79 according to de Aranzadi in the graphic curve published by the latter anthropologist, who, by the bye, is himself a Basque; there are two distinct maxima, one at 76 and the other at 80, indicating, probably, that there are at least two elements in the group. The French Basques are on an average three-quarters of an inch shorter than their Spanish brethren, 1657 mm. (5ft. 5¼ins.) and 1638 mm. (5ft. 4½ins.) respectively. Both branches of the stock have a similar very characteristic head; the cranium is distinctly long even in the most brachycephalic subjects, and is enormously swollen in the temporal region, a character which is absolutely peculiar to this people, the forehead is high and straight and narrow below, the face is very elongated and has the shape of an inverted triangle, the chin being thin and pointed; the nose is correspondingly long and narrow.

Certain anthropologists have claimed that those Basques who live north of the Pyrenees more nearly represent the primitive stock, while the same has been asserted for those south of that range. De Aranzadi thinks that those Spanish Basques with dark hair and eyes and a rather narrow head and of middle stature are of true Iberian origin and are related to the Berbers. Those with darkish brown hair and greenish hazel eyes, a broad head and low stature are, according to him, of Ugrian or Finnish descent. G. Buschan, in a recent number of *Globus* (Bd. lxxix. p. 123), regards it as highly probable that the Basque race resulted from a crossing of the short-heads of the earliest prehistoric time, who probably wandered from Asia into Europe, with the long-headed indigenous Mediterranean race. The first of these two constituents he recognises as the race of Grenelle (French authors) or as the type of Sion or Disentis (His-Rütimeyer) or as the celts of Broca. Buschan has overlooked the fact that Canon Isaac Taylor, in his "Origin of the Aryans," had suggested this same explanation in 1890 and Beddoe had alluded to it in his "Anthropological History of Europe" in 1893. De Aranzadi recognises a third element with light hair, blue eyes, narrow head and tall stature, which is a later addition of Kymric or Germanic origin, and he suggests that this element is related to the accursed race of the Cagots who were isolated from their neighbours and had a separate church door for themselves.

Collignon, who has made many brilliant studies in the anthropology of France, draws attention to the very anomalous relation that exists between a cephalic index of 82·5, which is clearly brachycephalic, and a cranial length as great as 191 mm. He is of opinion that this permits us to look for the affinities of the Basque race more in the direction of the long-headed races; the Nordic, or Teutonic, being clearly out of the question, relationship must be sought among the Mediterranean group of peoples rather than in the direction of the brachycephals of France and of Central Europe. Collignon's view is that the Basque type is a variety of the Mediterranean race that has for a long period of time been geographically isolated, and the retention of a difficult and uncouth language has formed an equally efficient linguistic barrier. These factors induced in- and in-breeding, and a well-marked human variety has resulted. Collignon's contention that the French Basques more nearly represent the primitive stock is now generally admitted; the head of the Spanish Basques has been narrowed and their stature diminished by mixture with Spaniards who had been driven into the mountains by the Moorish invasion. Those who desire to learn more about this paradoxical people will find numerous references to the literature in the valuable appendix to Ripley's "Races of Europe," and additional titles are given by Buschan in *Globus* (Bd. lxxix. February 28, 1901).

A. C. H.

THE DIAGNOSIS OF PLAGUE.[1]

I HAVE no doubt that the plague expert, who has seen epidemic plague in the East, will think it unnecessary on the part of a bacteriologist to ask, What is plague? for is not plague, as it occurs in China, India, at the Cape, and other parts weekly, nay, daily, by the score of cases, quite readily diagnosed by its clinical features and by its pathology? No one can have any doubt about this being so; that is to say, when plague appears in a locality in epidemic form, the diagnosis of any new case does not offer much difficulty; nor would there be experienced much difficulty in diagnosis by etiological, clinical, pathological and bacteriological methods of a case, or of cases, occurring in a ship coming from a plague-infected port: as, for instance, the cases that occurred in connection with a vessel which arrived about the middle of January in the port of Hull—cases which belonged to the pneumonic type, and which from the outset were, or ought to have been, at once diagnosed as such.

The difficulty in diagnosis commences when you have a single or a first case occurring, where either the etiological data are not satisfactory, or where the clinical history and symptoms are not distinct and not typical. The cases of two sailors recently examined illustrate these two difficulties.

The outcome of the bacteriological analysis of one sailor who arrived in London in October 1900 was that the case was plague. In the second case a plate made with a small droplet of pus from a swelling yielded, besides staphylococci and streptococci, a considerable number of colonies of the *bacillus pestis*. Tests by subcultures and animal experiments (both as subcutaneous and intra-peritoneal injections) proved this conclusively.

A third case is that of a boy that had recently occurred in one of the London hospitals. This much is certain, that the boy suffered from an illness the symptoms of which to a large degree were compatible with true plague; that etiologically no satisfactory evidence was forthcoming to elucidate the disease. The bacterioscopic evidence, which in certain respects supported the diagnosis plague, in another essential respect—animal experiment—negatived it; and I would particularly draw attention to the total absence of any microbes in the pus of the suppurating bubo of the boy in the later stages of his disease, and to the total absence of agglutinating action of his blood in the convalescent stage.

Apart from the difficulties in diagnosis of isolated cases, there are to be gathered, I think, several interesting and instructive facts from the cases hitherto mentioned.

In the first place, it is a fact that neither of the ship-borne cases mentioned above gave rise to infection in other persons, although during the whole journey they were freely intercommunicating with other members of the ship's crews. It will be no doubt said that *pestis ambulans*, the mild form with which, at any rate, one of those two cases compares, is known to possess only slight infectivity, and this infectivity might be referable only to the matter of the open and discharging bubo. In the two cases mentioned the number of *bacilli pestis* were still considerable, and in one at least of the cases there was a history of severe illness previous to arrival in English ports. And I would, in this connection, express a *primâ facie* strong scepticism as to the alleged high degree of infectivity of the bubonic type of plague in general. In the case of the pneumonic and septicæmic type, a high degree of infectivity is in complete accordance with the bacteriological facts and with the wide distribution of the plague bacilli in, and the copious discharge from, the body of the patient. In the pneumonic type, the exudation of the inflamed lung and the expectoration teem with the plague bacilli; in the septicæmic or hæmorrhagic form the blood contains an abundance of the bacilli, hæmorrhages occur in the membranes of the alimentary, respiratory and urinary organs; and therefore the voiding of plague bacilli is extremely great and their diffusion easy. But in the bubonic form, in the early phases of the disease, plague bacilli are rare in the blood; they are practically limited to the spleen and lymph glands, and as long as these latter do not open I do not see how they can be the agents of further infection. In the urine and in the alimentary canal they certainly cannot be demonstrated in a living state in this form of the disease. When the lymph glands, after the acute stage is passed, suppurate and open, then, no doubt, plague bacilli can and do become available.

[1] Abstract of a paper read before the Epidemiological Society on Friday, May 17, by Dr. E. Klein, F.R.S.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Dr. W. T. Brooks has been appointed Litchfield clinical lecturer in medicine.

Prof. H. A. Miers has been nominated to be a delegate of the University Press.

Mr. P. A. Barnett has been appointed an examiner in the theory, history and practice of education.

Profs. H. A. Miers and W. F. R. Weldon have been appointed examiners for the Burdett-Coutts Scholarship.

The Report of the Bodleian Library, just issued, shows that the accessions to the library during 1900 were the second largest on record.

The Junior Scientific Club held their 225th meeting on Friday, May 10. Prof. Odling read a paper upon the detection of arsenic.

Mr. E. L. Gill, of the Owens College, Manchester, has been appointed curator of the Hancock Museum by the committee of the Natural History Society of Northumberland, Durham and Newcastle-upon-Tyne.

The late Mrs. Morton Sumner has by her will bequeathed to Bedford College for Women 4000*l.* and a large number of books specially relating to geology, general literature and art; also a valuable collection of mineralogical specimens.

A FACULTY OF COMMERCE is to be established in connection with the University of Birmingham, and the council of the University are prepared to appoint a professor, at a salary of 750*l.* a year, to organise a course appropriate for students preparing to take a lead in commercial pursuits or to become consular representatives or holders of administrative posts abroad or in the colonies. The aims and scope of the work of the new Faculty are outlined in a document drawn up by the principal, Dr. Oliver Lodge, and containing suggestions which should meet with general approval. There can be no reasonable doubt as to the need for the cultivation of scientific sympathies among men engaged in manufacture, commerce and public affairs. "If our country is to keep pace with others," remarks Dr. Lodge, "we have to provide in every post a highly-educated man, skilled in many business relations, as Consul, whose duty it shall be to understand the conditions of each trade, to realise how it may be improved or increased, and to make annual or more frequent reports, either to the Board of Trade or to local Chambers of Commerce, or both." The more administrators, officials and men of business we have capable of realising this ideal the better it will be for our national welfare; but the best way to provide the educational basis has yet to be decided. Dr. Lodge suggests that commercial education must centre round a school of Economics—understood in its widest sense—but this may be doubted, and we believe that it would be better to keep this school out of the early stages of the scheme. Too much importance seems to be attached to preliminary knowledge of "Arts" and other subjects required of students in the Commercial Faculty. It is suggested that "The preparatory training in fact should be a wide and comprehensive one including a little science as well as a good deal of Arts." To our thinking, however, a little science is not enough, and what is essential in the preliminary education is not the accumulation of information so much as the training of the mind to acquire and assimilate knowledge. Geography is not to be considered as a separate science in the new Faculty, and its various aspects will be surveyed by the professors of history, economics and geology. Dr. Lodge makes a number of other suggestions which, if adopted, will give the new Faculty a character worthy of the new University.

The paper on "School Work in Relation to Business" read before the Society of Arts on May 8, by Sir Joshua Fitch, and printed in the Society's *Journal* for May 10, contained an expression of views with which many people will find themselves in agreement. The fundamental idea, illustrated by reference to several subjects, seems to be that too much attention is given in schools to the application of rules and too little to the development of common sense. For instance, in arithmetic the pupils are given a number of empirical rules and are drilled in working questions based upon them, but they are taught next to nothing of the theory of number or of arithmetical operations. The average pupil is happy if the teacher will tell him whether he has to multiply or divide to work a simple question, and he asks helplessly what rule he should use when he is given a problem. But the pupil who has learned arithmetic as a science rather than as a collection of artifices for the working out of problems is in a condition in which he can find his own rules. Instead of regarding such processes as multiplication of fractions and extraction of square roots as a kind of numerical conjuring and legerdemain, he feels that his operations have a reasonable basis. The advantage of such knowledge is that it enables the pupil to invent his own method of dealing with problems and to adapt himself readily to any arithmetical work he may have to do later in a business house. Arithmetic as usually taught does nothing but develop mechanical facility in working sums, whereas it ought to be used to bring out thought and inventiveness.

Passing to measurements of length, volume and mass, Sir Joshua Fitch held with most of us that the metric system ought to take a more prominent place in the arithmetic course than is usually assigned to it, because of its increasing use both in science and manufactures. Then geography is a subject which is held in small favour in the public schools and in most secondary schools, yet when well taught it can be made, both from the educational and commercial point of view, one of the most fruitful of school exercises. Finally, no subject consciously designed to meet the needs of the shop or office should be taught in a primary school. The chief object should be education and the development of originality, rather than the acquisition of information and manipulation of rules. According to Sir Joshua Fitch the course of work in such a school should include "arithmetic in its principles, rapid calculation, the metric system, oral and written composition, industrial geography, and also some exercises in thinking about social economics and the way in which conduct and character tell upon the future honour and usefulness of the citizen." At the other end of the educational ladder are the universities, to which, it was held, we ought to look for more guidance than they have yet ever afforded in the solution of the great problem—the relation of scholastic culture to the duties of active life.

SCIENTIFIC SERIALS.

American Journal of Science, May.—Studies of Eocene mammalia in the Marsh collection, Peabody Museum, by J. L. Wortman.—On the velocity of chemical reactions, by W. Duane. A description of two physical methods for following the velocity of a chemical change occurring in solution. In one of these the solution to be studied is placed in a wedge-shaped hollow prism and compensated with a similar wedge, the chemical change being followed photographically. A diagram is given showing the inversion of sugar as followed by this method. In the second method the change of volume of the solution is followed in a large thermometer.—The transmission of sound through porous materials, by F. L. Tufts.—On a yoke with intercepted magnetic circuit for measuring hysteresis, by Z. Crook. A description of a new form of yoke possessing certain advantages over the ordinary types. It gives practically a perfect hysteresis cycle, and can be used for studying the demagnetising action of electric currents without interrupting the magnetic circuit or varying it by means of a solenoid.—Mineralogical notes, by C. H. Warren. Crystallographic measurements and chemical analyses of anorthite crystals from Franklin Furnace, felspar crystals from Raven Hill, Colorado, iron wolframite from Dakota, and pseudomorphs of wolframite after scheelite from Trumbull, Conn.—On the expansion of certain metals at high temperatures, by L. Holborn and A. L. Day. Bars of metal 500 millimeters long were used, and enclosed in a porcelain tube heated electrically. The temperatures were measured with the thermocouple and ranged from 250° C. up to 1000° C. in the case of platinum, and in other cases to as high a temperature as the properties of the metal under examination would permit. Results are given for platinum, palladium, silver, nickel, constantan, wrought iron and steel.

American Journal of Mathematics, xxiii. 2, April.—The cross-ratio group of 120 quadratic cremona transformations of the plane. Part 2: Complete form-system of invariants, by H. E. Slaught, is the continuation of a memoir by the author which appeared in vol. xxii. (pp. 343–388). The text is accompanied by a large number of tables.—Memoir on the algebra of symbolic logic, by A. N. Whitehead, is a purely mathematical investigation, taking its rise in Boole's laws of thought. The credit of perfecting its laws of operation is assigned to C. S. Peirce and to Schröder. The keynote, according to the author, is the prominence given in his memoir to three ideas, viz. that of the "invariants" of a function of independent variables, that of "prime functions of independent variables," and that of the theory of "substitutions" of independent variables for independent variables. The last idea connects the algebra with the theory of groups and opens out a large field for investigation in that direction. The memoir, which occupies much space (27 pp.), is to be concluded in a subsequent number.—V. Snyder contributes a short note on a special form of annular surfaces. —On the transitive substitution groups whose order is a power of a prime number, by G. A. Miller, is a further contribution to a branch of mathematics for which the author has already done so much excellent work.—Geometry on the cubic scroll of the second kind, by F. C. Ferry, is a first instalment. Its object is to give a detailed treatment of several of the more interesting questions connected with the geometry of this scroll, and especially to consider the surfaces which can be passed through any curve on the scroll, so far as the order of those surfaces and the natures of the residual intersections are concerned. References are given to many memoirs bearing on the subject.

SOCIETIES AND ACADEMIES.

Royal Society, March 7.—"On the Heat dissipated by a Platinum Surface at High Temperatures. Part iv.—High-pressure Gases. By J. E. Petavel, A.M.I.C.E., A.M.I.E.E., John Harling Fellow of Owens College, Manchester. Communicated by Prof. Schuster, F.R.S.

The rate of cooling of a hot body in gases at pressures up to one atmosphere has received considerable attention, but with regard to gases at high pressures practically no data were up to the present available.

The present experiments were carried out with a horizontal cylindrical radiator contained in a strong steel enclosure, the enclosure being maintained at about 18° C. by a water circulation.

It is shown that the rate at which heat is dissipated by the radiator may be expressed by the following formula—

$$E = ap^{\alpha} + bp^{\beta}\vartheta,$$

where E = emissivity in C.G.S. units = total amount of heat dissipated expressed in therms (water-gramme-degrees) per square centimetre of surface of radiator per second; p = pressure in atmospheres; ϑ = the temperature of the radiator minus the temperature of the enclosure, or in other words the temperature interval in degrees Centigrade.

The gases studied are oxygen, hydrogen, air, nitrous oxide and carbon dioxide. In the case of the first three the formula holds good between 7 and 120 atmospheres and between 100 and 1100° C.

All the gases studied showed a rapid increase of the effective conductivity with the pressure.

Physical Society, May 10.—Prof. S. P. Thompson, president, in the chair.—A paper on applications of elastic solids to metrology was read by Dr. Chree. The object of the present paper is to exemplify the bearing of elasticity on physical measurements. Many of the results depend ultimately on a previous paper by the author, in which expressions were obtained for the mean strains and for the change in total volume of any homogeneous elastic solid acted on by any given system of forces throughout its mass or over its surface. The effect of the pressure of a surrounding medium of constant density upon the shape and volume of an isotropic solid is considered, and the theory is extended to the case of an æolotropic solid in a medium of varying density. The change in volume of the material of the walls of a flask containing liquid is next investigated, and it is shown that the change is independent of the thickness of the walls, the mean expansion per unit of volume being inversely proportional to the whole volume. Whether the alteration consists of an increase or a decrease depends upon the dimensions of the vessel. We cannot, in general, determine the effect on the internal capacity of a vessel due to the pressure of contained liquid, but if the walls are coaxial right circular cylinders, the common axis being vertical, the solution is possible. As a numerical example a glass tube 12·7 cm. high, 10 cm. internal diameter and 1·5 mm. thick would hold 0·11 grammes more mercury than it would if inelastic. The solution is possible in the case of a spherical shell, and this problem is also investigated in the paper. The author next considers the application of the theory of elasticity to standards of length, and to give a more exact idea of the problems actually occurring in metrology he deals particularly with five forms—the standard yard, the international prototype metre of X section, a working standard belonging to the Bureau International, and two deflection bars used in magnetometers. Most modern standards are supported, not over the whole lower surface, but either on two symmetrical rollers or on three points. In using standards of length it is the horizontal projection of the graduated surface that usually concerns us, and it is proved that unless we deal with a very long bar the difference between the chord and the arc is very small. The curvatures and lengths of bars supported in various ways, both loaded and unloaded, are treated at length, and it is shown that by a proper arrangement of supports the alteration in length between two points due to bending can be rendered so small as to be of no practical importance. In the metre prototypes of X section the divisions occur on the neutral surface and their distance apart is unaffected by stretching of the material. In the case of magnetometer deflection bars it is advisable to have the magnet light and as near to the bar as possible. Mr. Watson said that it was usual in deducing the radius of a coil from the measurement of its circumference with a steel tape to diminish the result by half the thickness of the tape. He would like to know if this was the right correction to apply. In measuring the circumference of a cylinder it is necessary to wind the tape in a spiral so as to bring the divisions side by side. This gives a result which is too great, and not too small as might at first sight be imagined. Dr. Lehfeldt asked if the work of the author could be used to determine the pressure corrections of thermometers. He would like to ask why it was necessary to use supports instead of allowing a standard to rest on a flat surface. The chairman said that the paper was important because of its bearing on the question of the relation between the units of different nations. He drew attention to the alteration of the factor converting metres into inches, and asked if it was due to alterations in the properties of matter or to errors of observation. The two legal definitions of the gallon differ by an appreciable amount, and it would be interesting to know if this discrepancy could be due to changes in the volume of measures due to the liquids contained by them. Dr. Chree, in reply to Mr. Watson, said the correction would depend upon the diameter measured, because that determined the curvature of the tape and, therefore, the stretching produced. In reply to Mr. Campbell, the author stated that direct experiments had been made upon the bending of bars and they agreed well with theory. The correction formula obtained for a thermometer is similar to the ordinary one used. A bar is usually supported so as to remove the uncertainty of the distribution of surface pressure when it rests on a flat surface not a true plane. In reply to the president, Dr. Chree said that the alteration of the factor converting metres into inches was probably due to errors of observation on account of the width of the divisions of the standard yard, and on account of the difficulty of obtaining the bar at the standard temperature of 62° F.—A paper by J. Rose-Innes and Prof. S. Young, on the thermal properties of isopentane compared with those of normal pentane, was read by Mr. Rose-Innes. In previous papers the authors have investigated experimentally the thermal properties of isopentane and normal pentane and have stated certain conclusions from their observations. The present paper gives the conclusions reached after a more exhaustive examination of the experimental results of the former papers. The quantity $RT - pv$ at any volume and temperature is called the departure from Boyle's Law at that point, and it is found that there is a constant ratio between the departures from Boyle's Law of isopentane and normal pentane at the same volume and temperature. To test the law a probable value of the ratio was determined, and by means of it a large number of values of pv for isopentane were calculated from results for normal pentane. These calculated values fall upon the same curve as the observed values and agree with them to within about 1 per cent. The authors are confirmed in their previous conclusion that the difference of pressure between two isomeric substances at the same temperature and volume involves the same power of the density as the first deviation from Boyle's Law, *i.e.* the second power. Mr. J. M. Gray said the numbers obtained would be valuable to him and he would make use of them in his calculations. He was sorry, however, that the authors had dealt with empirical formulæ instead of rational formulæ deducible from the theory of gases. Dr. Chree asked how the temperatures were measured. Mr. Rose-Innes said that recourse had been had to empirical formulæ because they found theoretical formulæ useless. He gave examples of the failure of well-known equations to satisfy experimental results. The temperatures were measured with a constant volume air thermometer, a small correction less than the errors of experiment being employed to reduce the readings to the thermodynamic scale.—The Society then adjourned until May 31.

Chemical Society, May 2.—Prof. Emerson Reynolds, president, in the chair.—The following papers were read:—The synthetical formation of bridged-rings. Part I. Some derivatives of bicyclopentane, by W. H. Perkin, jun., and J. F. Thorpe. Trimethylketobicyclopentanedicarboxylic acid,

$$\mathrm{CMe_2}\left\langle\begin{array}{l}\mathrm{C(CO_2H).CMe.CO_2H} \\ \;\mid \qquad\qquad \mid \\ \mathrm{CH} \text{———} \mathrm{CO}\end{array}\right. ,$$

when digested with potash, yields the lactone of trimethylhydroxybutanetricarboxylic acid,

$$\mathrm{CO}\left\langle\begin{array}{l}\mathrm{O—C(CO_2H).CHMe.CO_2H} \\ \qquad \mid \\ \mathrm{CH_2.CMe_2}\end{array}\right. ,$$

the anhydride of which is converted into the anhydride of a stereoisomeric acid by distillation. Ethyl dimethyldicarboxytrimethylenemalonate, $\mathrm{CMe_2}\left\langle\begin{array}{l}\mathrm{C(CO_2Et).CH(CO_2Et)_2} \\ \mid \\ \mathrm{CH.CO_2Et}\end{array}\right.$, is similarly hydrolysed by potash giving the lactones of the two isomeric dimethylhydroxybutanetricarboxylic acids,

$$\mathrm{CO}\left\langle\begin{array}{l}\mathrm{O—C(CO_2H).CH_2.CO_2H} \\ \qquad \mid \\ \mathrm{CH_2.CMe_2}\end{array}\right.$$

and

$$\left.\begin{array}{l}\mathrm{CO_2H.CH.CMe_2} \\ \;\mid \\ \mathrm{O—CO—}\end{array}\right\rangle \mathrm{CH.CH_2.CO_2H}.$$

—Lead silicates in relation to pottery manufacture, by T. E. Thorpe and C. Simmonds. Lead silicates or borosilicates, or complex silicates of lead and other metals, can be used instead of the oxides or carbonates as a means of introducing lead into pottery glazes. It is generally recognised that the employment of lead silicates for this purpose on the Continent has greatly tended to minimise the risk of lead-poisoning; this is due to the fact that the lead silicates used in the continental factories are of a high degree of insolubility so far as the lead is concerned. On examining a number of lead silicates used or proposed for use in England, many were found to be as easily attacked by dilute acids as the oxides or carbonates. The condition on which the insolubility of the lead depends was found to be, primarily, the existence of a certain ratio between the whole of the base-oxides, on the one hand, and the whole of the acid-oxides on the other. Provided that this ratio,

$$\frac{\text{number of acid molecules}}{\text{number of base molecules}},$$

falls within certain definite limits, the amount of lead extracted by dilute acids, such as the hydrochloric acid in the gastric juice, is always small.—The preparation and properties of 2 : 6-dibromo-4-nitrosophenol, by M. O. Forster and W. Robertson. This substance is prepared by the action of potassium hypobromite on paranitrosophenol in potassium hydroxide solution; a number of its derivatives are described.—The chlorination of toluene, by W. P. Wynne.

Geological Society, April 24.—Mr. J. J. H. Teall, V.P.R.S., president, in the chair.—Notes on two well-sections, by the Rev. R. Ashington Bullen. The well-section at Southwark passes through sand and gravel, &c., 34 feet, London clay 75 feet, Woolwich and Reading beds 56 feet 9 inches, and Thanet sand 36 feet 6 inches, into chalk which was bored to a depth of 148 feet. The well-section at Dallinghoo post-office, near Wickham Market (Suffolk), penetrated 53 feet of blue chalky boulder-clay, into 20 feet of sand and gravel, water being found at a depth of 79 feet.—On the geological and physical development of Antigua, by Prof. J. W. Spencer. Antigua and Barbuda rise from the bank which occupies the north-eastern portion of the chain of the Lesser Antilles. The part of the bank on which these two islands are founded is submerged to the very uniform depth of about 100 feet, but from other island-groups it is separated by depressions of 1800 to 2500 feet. It is concluded from the erosion-features of the region that the region was an extensive land-surface, probably at least 2000 feet higher than now, during the Mio-Pliocene period, and was reduced by denudation to a comparatively low elevation before the close of that time. This was followed by a submergence (the Friar's Hill) to a depth of 200 feet below the present altitude. At the close of the Pliocene period there was another elevation to an extent probably exceeding 3000 feet, as shown by the channels on the submarine plateau between Antigua and Guadeloupe. This did not continue sufficiently long to complete the dissection of the tablelands, and consequently the Antigua-Barbuda mass remains intact. Then followed a subsidence culminating in a 75-foot submergence, a re-elevation to 100 feet above the present level, when the shallow channels in the submarine bank were formed, and possibly one or two other small movements.—On the geological and physical development of Guadeloupe, by Prof. J. W. Spencer. The Guadeloupe group is separated from the Antigua and Dominica groups by depressions 2000 feet deep. Much of Guadeloupe itself consists of eruptive rocks, evidently as old as the igneous base of Antigua. The land-surface during the Mio-Pliocene period appears to have been 2000 feet above the present level, but it was submerged 200 feet at the close of the Pliocene period during the accumulation of the Lafonde and Lower Petit Bourg gravels and loams. There was a re-elevation of about 3000 feet in the early Pleistocene period, and during this epoch *Elephas* could have crossed from the continent. This was followed by a depression to 100 feet or more below the present level, a re-elevation to 150 feet, submergence below the present level with growth of corals, and the elevation of these to six or eight feet above the sea.—On the geological and physical development of Anguilla, St. Martin, St. Bartholomew and Sombrero, by Prof. J. W. Spencer. Deep channels, not less than 1800 feet deep, separate the bank on which this group is founded from the banks to the north and south. The St. Martin plateau was a land-surface throughout the Mio-Pliocene period, during the earlier part of which it appears to have stood 2500 feet above its present level, and was probably connected with the now neighbouring insular masses, from which it was disconnected by denudation during a very long period of atmospheric activity, followed by a subsidence, so as to bring the present surface of the submarine banks to a level so low that the undulating features of a base-level of erosion could be formed on them; for, during the period when the deep and broad depressions on the Antillean chain were being fashioned, the now isolated island-groups stood out as table-mountains, which were slowly being eaten away by atmospheric agents. There was next a subsidence to about 200 feet below the present level, about the close of the Pliocene period, followed by a re-elevation to 3000 feet, as shown within the area, but in reality much more. It was during this early epoch of the Pleistocene that the great rodents described by Prof. Cope reached here from South America, but the race continued to live here sufficiently long to give rise to distinct species.—On the geological and physical development of the St. Christopher Chain and Saba Banks, by Prof. J. W. Spencer. The St. Christopher (St. Kitts) ridge rises from 2000 to 2800 feet above the submarine Antillean plateau, and is for the most part covered with shallow water, except between St. Kitts and Montserrat, where a depression reaches 2592 feet, and between Statia (St. Eustacius) and Saba, where it reaches 1200 feet. Relics of old igneous formations are found on the islands, but in most places they are covered by more recent volcanic formations. The group appears to have had the same physical history as the neighbouring groups of islands.

May 8.—Mr. J. J. H. Teall, V.P.R.S., president, in the chair.—The influence of the winds upon climate during the Pleistocene epoch; a palæo-meteorological explanation of some geological problems, by F. W. Harmer. The views taken in this paper afford a simpler explanation of geological facts than those usually adopted. Instead of supposing that the climatic changes of the Great Ice Age, several times recurrent at intervals of a few thousand years, were due to astronomical or physical causes, it is suggested that the climate of the northern hemisphere being, from some unexplained cause, colder than that of our era, conditions of comparative warmth or cold may have been more or less local, affecting the great continental areas at different periods.

Entomological Society, May 1.—The Rev. Canon W. W. Fowler, president, in the chair.—Mr. C. G. Barrett exhibited for Mr. H. W. Vivian a specimen of *Xylophasia lateritia*, Hufn., a species not hitherto recorded in the British Islands, taken in South Wales by Mr. W. E. R. Allen; also *Deiopeia pulchella*, from the same district; *Dianthecia luteago*, var. *barrettii*, from one of the islands off the Glamorganshire coast, and varieties of *Eupithecia virgaureata*, much blackened, *E. lariciata*, *E. satyrata* and *E. exiguata*, taken by Mr. Vivian.—Mr. M. Jacoby exhibited specimens of *Heliocopris gigas*, L., from Mashonaland, and *Silpha biguttata*, Fairm., from Patagonia.—Sir George Hampson exhibited two females of an apterous *Lasiocampid* from the Transvaal, with cocoon and ova bred by Colonel J. M. Fawcett, 5th Lancers. The larva is very much like that of the British *Lasiocampa rubi*. The female does not emerge from the cocoon, its antennæ being aborted and all the joints coalesced with a flabellate organ with slight striæ indicating the joints; the fore tibiæ short with traces of tibial claws. The male is unknown.—Mr. H. St. J. Donisthorpe exhibited specimens of *Ripersia tomlini*, Newst., a coccid new to Britain, taken among *Lasius niger* at Portland in April 1900.—Mr. C. P. Pickett exhibited aberrations and varieties of *Lycaena bellargus*, *L. corydon* and *L. astrarche*, taken by him in August 1900 at Folkestone and Dover.—Mr. H. Goss exhibited a gynandromorphous specimen of *Lycaena bellargus* which he had taken at Reigate in June 1900. It had the characters of a male in the right wings, and the characters of a female in the left wings, which were, however, not entirely free from the blue scales of the male.—Dr. Chapman exhibited a cocoon of *Antheraea mylitta* and a flint from Redhill—two objects with practically nothing in common. Whilst dissenting *in toto* from those who see nothing in many cases of mimicry but accidental resemblance, he presented them with this as a case undoubtedly in accordance with their views, the cocoon and the flint being remarkably alike.—Prof. Poulton exhibited an apparatus invented by him to determine the strength of the formic acid discharged by the ant in defence of its nest. A discussion followed, in which Prof. Hudson Beare said he had found his skin affected by *Formica rufa*, and Mr. Donisthorpe that the skin had been removed from his hand and his gloves burnt in patches after being placed in the nest of the same species.—Mr. F. Enock exhibited numerous specimens illustrative of the metamorphoses of dragon-flies.—Mr. Enock read a paper entitled "The Metamorphoses of *Æschna cyanea*, illustrated by the electric lantern with photographs taken from life."—Sir George Hampson, Bart., communicated a paper on the classification of a new family of the Lepidoptera; Mr. Martin Jacoby a paper entitled "A further contribution to the knowledge of African Phytophagous Coleoptera"; and Mr. Gilbert Arrow a paper entitled "The Carabid genus Pheropsophus; notes and descriptions of new species."

Mathematical Society, May 9.—Dr. Hobson, F.R.S., president, in the Chair.—Major MacMahon, R.A., F.R.S., communicated two notes, on the series whose terms are the cubes and higher powers of the binomial coefficients and a case of algebraic partitionment.—Mr. J. B. Dale read a paper on the product of two spherical surface harmonics and Mr. H. M. Macdonald communicated a note on the zeros of the spherical harmonic $P_n^{-m}(\mu)$.—A note on a property of recurring series by Mr. G. B. Mathews, F.R.S., was communicated from the chair.

Royal Meteorological Society, May 15.—Mr. W. H. Dines, president, in the chair.—Mr. Rupert T. Smith read a paper on the periodicity of cyclonic winds, which was the result of a discussion of his own observations made in the neighbourhood of Birmingham during the twenty-six years 1874-1899. The equinoxes do not appear to be very stormy periods, but from the author's tables it is shown that the greatest frequency and force of cyclonic wind occurs some two weeks before the spring equinox and some three weeks after the autumn equinox.—Mr. W. Marriott gave an account of the bequest by the late Mr. G. J. Symons, F.R.S., to the Royal Meteorological Society. By his will Mr. Symons bequeathed to the Society his Cross of the Legion of Honour, the gold Albert Medal awarded to him by the Society of Arts, the testimonial album presented to him in 1879 by the fellows of the Royal Meteorological Society, and the sum of 200*l.*, as well as such of his books, pamphlets, maps and photographs of which there were no copies in the Society's library. Mr. Marriott stated that from Mr. Symons's valuable collection he had selected for the Society over 5000 books and pamphlets and about 900 photographs. A large number of the books were old and rare works, 750 bearing dates previous to 1800, while 8 were as early as the fifteenth century. By this bequest the Royal Meteorological Society now possesses the most complete and extensive meteorological library in existence.

CAMBRIDGE.

Philosophical Society, May 6.—Prof. A. Macalister in the chair.—The oscillations of a fluid in an annular trough, by Mr. B. Cookson.—Some experiments upon beams under endlong compression, by Mr. H. E. Wimperis.—Liveingite, a new mineral from the binnenthal, by Messrs. R. H. Solly and H. Jackson. This new mineral, to which the name "Liveingite" has been given in honour of Prof. G. D. Liveing, F.R.S., is a new member of the group of sulpharsenites of lead which comprise Sartorite $PbS + As_2S_3$, Rathite $3PbS + 2As_2S_3$, Dufrenoysite $2PbS + AS_2S_3$ and Jordanite $4PbS + As_2S_3$.—Note on the magnetic deflection of kathode rays, by Mr. H. A. Wilson. In this note the results of measurements of the magnetic deflection of kathode rays proceeding from kathodes of different metals are recorded. The results show that e/m is independent of the nature of the metal forming the kathode.—On the diminution of the potential difference between the electrodes of a vacuum tube produced by a magnetic force at the kathode, by Mr. J. E. Almy.—An attempt to discover radiation from the surface of metals carrying alternating currents of high frequency, by Mr. O. W. Richardson. The experiments were suggested by the corpuscular theory of the conduction of electricity in metals. The radiation expected was of the nature of secondary Röntgen rays. It was sought to detect this by its photographic effect and by the conductivity it would produce in the surrounding air. The maximum current density at the surface of the wires used was 130,000 amperes per sq. cm. and was produced by the discharge of two Leyden jars connected to an induction coil. A sensitive method was used to detect the leak, which was shown to be not greater than that generally present in air.

DUBLIN.

Royal Dublin Society, February 20.—Mr. J. Holms Pollok in the chair.—In the absence of Prof. W. F. Barrett, F.R.S., Mr. R. J. Moss read a paper by the Rev. H. V. Gill, S.J., on the stratified discharge in Geissler tubes, which was communicated to the Society by Prof. Barrett.—Prof. J. Joly, F.R.S., read a note on the pseudo-opacity of anatase.

March 20.—Sir Howard Grubb, F.R.S., in the chair.—Sir Howard Grubb read a paper on a new collimating telescope sight for large and small ordnance.—A paper entitled "Variation—Germinal and Environmental," by Prof. J. C. Ewart, F.R.S., was communicated by Prof. D. J. Cunningham, F.R.S.—Mr. J. Holms Pollok read a paper on a new thermo-chemical notation.—Prof. W. N. Hartley, F.R.S., presented a paper on the conditions of equilibrium of hygroscopic and deliquescent salts of copper, cobalt and nickel.—Dr. W. E. Adeney read a paper on ultra-violet spark spectra from the Rowland's spectrometer in the Royal University of Ireland.—Prof. W. F. Barrett, F.R.S., exhibited a series of recent radiographs.

April 17.—The Earl of Rosse in the chair.—Prof. J. Joly, F.R.S., read a paper describing a new form of electric furnace. The furnace consists of a fire-clay crucible in the walls of which a platinum wire, wound in the form of a spiral, is imbedded and through which a current is passed. Very high temperatures, up to the softening of the clay, are obtainable. A pattern in which the charged crucible is placed within an outer fire-clay vessel or muffle, heated as described, is recommended. Here the crucible may be of platinum or any refractory material. A reflector surrounds the muffle. A minute pattern was also shown in operation designed to give an intense local temperature in certain experiments on the viscosity of silicates. These furnaces are sufficiently durable to be of value in many experiments where a prolonged high temperature is required, controlable with considerable accuracy and free from flame contamination.—Prof. Joly also read a paper on a new method of identifying minerals in rock-sections by their birefringence. The degree of thinness which it is necessary to confer upon rock-sections is attended with the evil that the value of birefringence as a means of diagnosis is largely restricted to substances of high birefringence, the polarisation colours of many of the most important rock-forming minerals thus being but little differentiated. To overcome this difficulty, while preserving to the section the desirable transparency, the author, by a simple addition to the petrological microscope, sends the polarised ray twice through the section. This is accomplished by means of an opaque illuminator, an arrangement furnished by many makers, consisting of an attachment above the objective, containing a totally reflecting prism illuminated by light received through a frontal aperture, and transmitting the ray downwards through the objective on the object being examined, from the surface of which it is reflected again into the microscope. In the present application of the illuminator to the petrological microscope a nicol is attached over the aperture, and the ray totally reflected and transmitted downwards within the objective is (sensibly) plane polarised. Beneath the rock-section a small mirror of speculum metal or silver is placed. The ray after its first passage through the crystal under examination is reflected by this mirror, and the incidence being nearly normal is again returned through the crystal, thus traversing it twice before reaching the eye. It can be demonstrated, with a double image prism and by colour observations on a plate of selenite overlapped upon itself, that the loss of phase does not interfere with the accuracy of the method. This mode of examination at once introduces discriminative differences into the tints of many important substances, as the monoclinic and triclinic felspars, quartz, &c., all former differences of retardation being, in fact, doubled in amount.—Prof. Hugh Ryan read a paper on the synthesis of glucosides, and, in conjunction with Mr. W. Sloan Mills, one on the synthesis of galactosides.—Mr. R. J. Moss made some interesting experiments with liquid air by means of the Hampson gas liquefying apparatus.

Paris.

Academy of Sciences, May 13.—M. Fouqué in the chair.—On a perfectly astatic galvanometer, by M. Lippmann. The needle of the galvanometer described is mounted in such a way that it can be placed in the plane of the magnetic meridian and under the action of the current tends to move parallel to itself. Under these conditions the earth's field exerts no opposing force to the action of the current, and the apparatus is perfectly astatic.—On the theorems of Hugoniot, the lemmas of M. Hadamard, and the propagation of waves in viscous fluids, by M. P. Duhem.—On the real integrals of differential equations of the first order in the neighbourhood of a singular point, by M. Henri Dulac.—On certain involutive relations, by M. Maurice Lelieuvre.—On a problem of d'Alembert, by M. F. Siacci.—On an experiment in electrical oscillations, by M. H. Pellat.—The permeability of nickel-steels in intense fields, by M. René Paillot. Three classes were examined—irreversible steels, reversible steels, and steels containing small quantities of chromium and manganese besides nickel. In the first of these the magnetic permeability sensibly increased in the intense fields; in the second case, the reversible steel, the permeability attained a value of 1·19 for a field of 4000 C.G.S. units, and remained practically constant up to 30,000 units.—On the laws of outflow of air in musical instruments, by M. Firmin Larroque.—On the aromatic organo-magnesium compounds, by MM. Tissier and Guignard. It is shown that the halogen benzene derivatives react with magnesium in a manner exactly analogous with the halogen compound of the fatty series. As examples of the generality of this method, the preparation of triphenyl-carbinol, dimethylphenyl-carbinol and diphenyl-ethylene are described. In all cases the yields are nearly theoretical.—The decomposition of albuminoids into protoplasmides, by M. A. Etard. Decalcified bone, submitted to a simple hydrolysis, gives three groups of substances: glycocoll, leucine and a little tyrosine; a syrupy material very soluble in methyl alcohol; and a substance quite insoluble in methyl alcohol. The last compound has been analysed and is named bos-osteoplasmide.—Differences in the constitution of the bile according to the age and fatty state of the animal, by M. R. L. Craciunu.—On the phosphoric acid of the soil, by M. Th. Schlœsing, jun. An examination of the amount of phosphates removable from certain soils by repeated extraction with water.—On the composition of amblygonite, by M. Henri Lasne.—Histological researches on the sporulation of yeasts, by M. A. Guilliermond. At the moment of sporulation there appears to be a sort of solution of the red grains contained in the vacuoles, these bodies appearing to behave in some respects as a reserve material.

DIARY OF SOCIETIES.

THURSDAY, May 23.

Royal Society, at 4.30.—On the Presence of a Glycolytic Enzyme in Muscle: Sir Lauder Brunton, F.R.S., and Herbert Rhodes.—On Negative After-Images and their Relation to certain other Visual Phenomena: S. Bidwell, F.R.S.—The Solar Activity, 1833–1900: Dr. W. J. S. Lockyer.—A Comparative Crystallographical Study of the Double Selenates of the Series $R_2M(SeO_4)_2, 6H_2O$.—Salts in which M is Magnesium: A. E. Tutton, F.R.S.—On the Intimate Structure of Crystals. Part V. Cubic Crystals with Octahedral Cleavage: Prof. W. J. Sollas, F.R.S.

Royal Institution, at 3.—The Chemistry of Carbon: Prof. J. Dewar, F.R.S.

FRIDAY, May 24.

Royal Institution, at 9.—The Aims of the National Physical Laboratory: Dr. R. T. Glazebrook, F.R.S.

SATURDAY, May 25.

Royal Institution, at 3.—The Rise of Civilisation in Egypt: Prof. W. M. Flinders Petrie.

TUESDAY, May 28.

Royal Photographic Society, at 8.—(1) Practical Tricolour Photography; (2) The Optics of Tricolour Photography: E. Howard Farmer.

Anthropological Institute, at 8.30.—Measurements of Crania from the Fly River: J. Gray.—Anthropometrical and Craniological Notes on the Eastern Papuans: C. G. Seligmann.—Remarks on the Present State of our Knowledge of the Ethnology of British New Guinea: Prof. A. C. Haddon.

THURSDAY, May 30.

Royal Institution, at 3.—The Chemistry of Carbon: Prof. J. Dewar, F.R.S.

Institution of Electrical Engineers (Society of Arts), at 8.—Annual General Meeting.

FRIDAY, May 31.

Royal Institution, at 9.—With the Allies in China: A. H. Savage Landor.

Physical Society, at 5.—On a Model which imitates the Behaviour of Dielectrics: Prof. Fleming, F.R.S., and A. W. Ashton.—(1) On the Resistance of Dielectrics and the Effect of an Alternating Electromotive Force on the Insulating Properties of India-rubber; (2) Note on the Electrification of Dielectrics by Mechanical Means: A. W. Ashton.

SATURDAY, June 1.

Royal Institution, at 3.—The Biological Characters of Epiphytic Plants: Prof. J. B. Farmer, F.R.S.

A NEW TREATISE ON PHYSICS.

A Treatise on Physics. By Prof. Andrew Gray, F.R.S. Vol. i. Pp. xxiii + 688. (London: J. and A. Churchill, 1901.) Price 15*s.*

A BRIEF abstract of the contents of this book will suffice to show at once the enormous amount of information it contains and the labour which has been expended on its production. Its aim is "to provide a treatise on physics which may serve for those who, beginning at the elements of the subject, wish to have in one book an account of theoretical and experimental physics which may be sufficient for most practical purposes of scientific and technical education." Accordingly, the first volume contains nearly 700 pages devoted to dynamics and the properties of matter.

The book commences with an account of the fundamental units of measurement. Then comes a long chapter of nearly 100 pages given to kinematics; this is followed by chapters on dynamics, work and energy; after this we have statics of solids and fluids, gravitational attraction, astronomical dynamics, and the tides. The theory of elasticity fills some 70 pages, to be followed by 30 pages on capillarity, while the book closes with a very short section on measurements and instruments. As a book of reference, a kind of encyclopædia of physics, the work will be most useful; whether a student who is really beginning the subject would profit by the attempt to peruse it is perhaps open to doubt. For such a student the whole is too condensed; the range of subjects enumerated above is ordinarily dealt with in some six or eight different books, and though there is much force in Prof. Gray's protest against "the division of a great subject like physics into isolated compartments," yet most beginners will find that the subjects dealt with need a fuller treatment than Prof. Gray can give them, at least so far as their elementary parts are concerned.

It should be noted that the book contains no examples for the student to work out. Now while at Cambridge the practice of setting problems may be carried too far, most teachers will agree that it is only by practice in working examples that the fundamental laws of a subject such as dynamics can be driven home to an ordinary student. An engineer has to apply his mathematics to the questions which are brought before him for solution in his practice. The problems of the examination room differ, no doubt, in a marked degree from those which occur in real life, but a man who has been trained to their solution has a better chance of success when he is faced by some practical difficulty to which he must apply his mathematics than one whose training has consisted solely in studying the book work of his subject. However considerations such as these deal with the general scheme of the work, they do not touch the question, how the scheme has been carried out.

In looking at a new book on dynamics the reader turns naturally to the sections dealing with the laws of motion, and here the treatment might, we think, be clearer.

The ideas of inertia, mass, momentum, force, are not easily grasped by a beginner. Prof. Gray commences by the consideration of stress, the mutual action between two bodies whose relative motions are undergoing change; he then goes on to Newton's first law, in which the word "force" is introduced; it would be well to explain that the "impressed forces" of the law constitute one aspect of the stress which has been discussed just previously, indeed it may perhaps be questioned whether it is desirable to introduce the term stress at all in this connection. Strictly, a stress is measured by the force applied per unit of area; it has the dimensions of force divided by the square of a length, and we might more strictly call the mutual action between a falling body and the earth a force rather than a stress.

We then have a section on inertia or mass, and here Prof. Gray does not seem quite happy in his treatment. We are told that we get the idea of inertia from the observation "that different bodies have, when placed in what we are justified by experience in regarding *as the same circumstances*, different accelerations." Then we are to take the inertia of a body "as a measure of the quantity of matter in the body or, as it is called, the body's mass, and we shall see (§ 144) that the comparison of masses thus obtained must agree with that carried out by weighing." Again, the inertias of two bodies are compared by comparing the accelerations produced by applying to each in turn for one second a spring with a given stretch; the inertias are said to be inversely as the accelerations. Thus inertia is used throughout as equivalent to mass or quantity of matter, and practically the second law of motion, which, however, is not introduced until a later stage, is assumed; the spring with a given stretch exerts a definite force, and this force is equal to the product of the inertia and acceleration.

Such a treatment is open to criticism; for one thing the experiment suggested is an almost impossible one to perform; it is better either to start from some such statement as that whenever two bodies are moving under conditions in which each is free from all action, except that which arises from the second body, all the circumstances of the motion are consistent with the supposition that the ratio of the two accelerations is a constant, and to define this constant as the reciprocal of the ratio of the masses.

If it be objected, as perhaps it fairly may be, that the conditions assumed are never realised, we may have recourse to experiments with an apparatus such as Prof. Hicks's ballistic balance, in which two bodies swinging as pendulums are allowed to impinge directly in such a way that they are both brought to rest; experiments with this show at once that the ratio of the two velocities with which the bodies are moving at the moment of impact is a constant so long as the bodies remain unchanged. We define the ratio of the masses of the bodies as the reciprocal of this constant, and thus we obtain a means of comparing masses without the introduction of the idea of force; moreover, it is easy to pass naturally from this to the idea of mass defined as measuring the quantity of matter in the body.

Thus, having obtained a knowledge of mass and velocity, we can introduce the idea of force as the time rate of change of momentum, using Newton's second law to define and measure force.

Prof. Gray is careful to explain that he does not look

F

upon force as a cause of motion. Thus, § 138, when dealing with a simple pendulum, he writes: "The idea that F, T" (certain quantities appearing in his equations) "on the left denote forces in the sense of causes of motion and that the expression on the right are effects is a fallacy." He does, however, permit himself to speak of stresses as causing motion; it would surely be better to avoid the idea of causation entirely; it is doubtful if anything is gained by the distinction between "stress," as used by Prof. Gray, and "force." The term stress does, it is true, call attention to the fact that the action it denotes is a mutual one between two or more bodies, and this is wanting in the term force. Still, is is difficult to be consistent in the matter; thus, § 146, in dealing with Atwood's machine, we read, "putting T for the mass-acceleration *due* to the force applied to either mass"—the italics are not in the original. When once it has been explained that forces are measured by mass-accelerations, might we not write more simply and with equal effect the words, putting T for the tension of the string?

Observation shows us that in many cases the mass-acceleration of a particle is a constant; if we know the value of this constant from the conditions of the problem we can, having given the initial conditions, determine the motion; we say, for brevity, that the particle is moving under a constant force. In other cases, it has been observed that the mass-acceleration is a known function of the position of the particle relative to other particles. This function can often be calculated without any knowlegde of the velocity or acceleration of the particle; thus, if there be a second particle at a distance r from the first, each will have a mass-acceleration towards the other equal to mm'/r^2 where m and m' are the masses of the two particles. This is the force under which either particle moves. Having given this force, by equating it to the mass-acceleration, and solving the equations we can determine the motion. Thus the resolution of any problem of motion of a particle falls into three parts: (1) We determine from the conditions the mass-acceleration in each of three rectangular directions; (2) We equate these to the analytical expression giving these mass-accelerations in terms of the coordinates of the particle and their differential coefficients with respect to the time; (3) We solve the resulting equations.

We may consistently employ the name force for the quantities determined under (1), and indeed may speak of them as the forces impressed on the particle without implying that they are the cause of the motion. This is done in the later sections of the chapter. One other criticism occurs in connection with the sections of the book immediately under review. Prof. Gray writes, § 134, "The word weight is used in two senses, in the sense of the quantity of matter in a body, and sometimes, though perhaps more rarely, in popular language as the downward force of gravity on a body in certain specified circumstances. It seems impossible to discard the former use of the term even in scientific speech, and therefore we shall use the word generally in this sense and in the latter sense speak of the gravity of a body."

Again, in the next section we find the sentence, "We may take the inertia of a body as the measure of the quantity of matter in the body or, as it is called, the body's mass."

Thus weight and mass are to be used as synonymous, contrary to the practice of writers on dynamics during many years past. Such a change, unless the grounds for it be very strong, must lead only to confusion, and the fact that weight is used ambiguously in daily life is hardly a satisfactory reason for the innovation which has been adopted.

We have referred at length to these few pages of the work because of the importance of the fundamental ideas and conceptions with which they deal. It is impossible to deal with the rest in the same manner, nor, indeed, is it necessary. The reader will find the book a storehouse of valuable information, which is generally put clearly and well; experience alone will show whether or no it is useful for students "beginning at the elements of the subject." However this may be, the book should be found in every physical library, and is sure to be frequently consulted.

TROPICAL CRUSTACEANS.

The Stalk-eyed Crustacea of British Guiana, West Indies, and Bermuda. By Charles G. Young, M.A., M.D., Dublin, Member of the Royal Irish Academy, lately of the British Guiana Medical Service. 8vo. Pp. xix+514; 7 plates, coloured, and numerous outlines. (London: Watkins, 1900.) Price 12*s.* 6*d.* net.

FROM the equator to thirty-five degrees north the western Atlantic, with its neighbouring shores and rivers, can supply a group of stalk-eyed Crustacea not easily surpassed in interest by such a fauna from any other region in the world. The descriptions relating to this group lie scattered over numerous treatises. Dr. C. G. Young has conceived the meritorious idea of bringing them together under one cover. He modestly speaks of his performance as a hand-list for the use of collectors. Handiness and usefulness should therefore be among its characteristic features. As it lays no claim to originality, the virtues of accuracy, completeness and condensation might have been expected. In place of these there is offered to the student a volume expansively and expensively printed; serious omissions are balanced by a parade of unneeded trivialities; whilst from one end to the other slovenliness prevails in the use of older authorities and neglect or ignorance of those that are more recent. Like the curate with a questionable egg at an episcopal breakfast table, one might say of this book that "parts of it are good, my lord," but no one can tell which parts without consulting the very authorities which its publication presumes to be out of reach.

The first page includes an old definition of the class Crustacea, informing us that in these animals the body is "composed of segments, in general very distinct, motile," and this is followed by hundreds of pages dealing with crabs, in which, as Dr. Young well knows, for many or most of the component segments the distinctness is almost null and the "motility" absolutely *nil.* The end of the story is on a par with its beginning. It treats of the Squillidæ, and describes four species, adopting the synopsis of the genera from the work of Brooks on the *Challenger* Stomatopoda, but calmly assigning to the genus Squilla two species which, according to that very synopsis, belong to Lysiosquilla. The discussion of a true Squilla from the coast of Yucatan by J. E. Ives in 1891, and the truly valuable report on the Stomatopoda of the *Albatross* by Dr. R. Payne Bigelow in 1894, were evidently unknown to Dr. Young. Naturally, therefore, he leaves unnoticed the species new or old in this or other orders recorded by those two writers. Perhaps his attention was too much concentrated on older essays, and, as these are often much less accessible than modern treatises, such a fault would deserve to be leniently regarded. It was, indeed, with some eagerness that the present reviewer, on first opening the book, turned to the excellent index for the name Glypturus. Of this genus Miss Mary J. Rathbun last year published a new species from Brazil. That is not in the region with which Dr. Young's work is concerned, but the genus was established long ago by Stimpson in the *Proceedings* of the Chicago Academy of Sciences, vol. i. p. 46, 1866, with repetition in the *Annals* of the Lyceum of Natural History of New York, vol. x. p. 120, 1874, for a species "not uncommon among the Florida Keys." Of this Dr. Young has nothing to tell us. He mentions, indeed, two species of the same family, *Callianassa occidentalis*, Bate, and *Callianassa major*, Say, but he was obviously not in a position to inform his readers that Stimpson instituted the genus Callichirus to receive Say's species, and he does not take the trouble to tell them that Bate's species was founded on a single leg, which left Bate himself doubtful as to its generic position.

On generic and specific names and lists of synonyms there are various opinions, but most naturalists agree that quoted names had better be quoted correctly, and that an author would do well not only to verify his references, but to give others a reasonable chance of verifying them after him. Dr. Young's adhesion to these views may be complete in principle, but is made very doubtful by his practice. The scope of his work scarcely required a "synonymy" for the term Brachyura, still he has been pleased to give one. It leads off with the information that the word was adopted by 'Leach, Latreille, Dana, Linné, Claus, Haswell, Miers,' Linné's name as a centrepiece reminding one of those Welsh genealogies which are reputed to have Adam halfway down the ancestral line. Where and when Linnæus changed his *Cancri Brachyuri* into Brachyura we are not told, and are never likely to be. The synonymy continues in separate lines with '*Brachyura*, H. Milne Edwards,' '*Cancri Brachyuri*, Lamarck,' '*Klistognatha*, Fabricius,' '*Tetrogonostoma*' bracketed with '*Trigonostoma*, Macleay.' Here again we are not told when it was that Fabricius changed the Kleistagnatha of his Supplementum into Klistognatha, and as for the implied but ungiven reference to Smith's "Illustrations of the Zoology of South Africa," there is confusion doubly confounded. In that work McLeay adopts and uses the term Brachyura in common, not only with half a dozen authors, but with half a hundred or an indefinite number. He divides the group into two tribes, and it is to these he assigns the names above quoted, with the difference that he spells the first of them correctly as Tetragonostoma. In dealing with genera and species Dr. Young shows no more ceremony than with the higher groups. He attributes *Podochela reisei* to Stimpson, A. Milne Edwards and Miers, though certainly the first and last write the specific name *riisei*, and Stimpson says that it 'was found at the Island of St. Thomas by Mr. A. H. Riise, after which indefatigable investigator of West Indian natural history we have named the species.' For the genus Ibacus, Leach, Spence Bate's spelling, Ibaccus, is adopted, and Leach is accused of having written Ibachus. *Cardiosoma carnifex* is attributed to Herbst, though he died long before the species intended was assigned by Latreille to Cardisoma. The young German naturalist, von Willemoes Suhm, who died on the *Challenger* expedition, is uniformly referred to as Suhn. The Pandalidæ are defined without any regard to the discovery published by Caullery and by Calman two years ago that the front feet in this family had been misdescribed. And, as if all this were not enough, the unhappy author re-introduces the name *Uca una*, Marcgravè de Liebstad, without mentioning the year 1648 as the date of it, and in defiance, or perhaps in ignorance, of all the trouble and accurate learning with which Miss M. J. Rathbun has shown that this typical West Indian species ought rightly to be called *Ucides cordatus* (Linn).

There are some interesting local names given. We are told, for example, that *Panulirus guttatus* is called in Barbados the "Guinea bird lobster." The pages have satisfactory margins. There is room, therefore, for a naturalist with leisure, by supplementary notes, corrections and verifications, to give the book a solid value.

T. R. R. S.

PRACTICAL INORGANIC CHEMISTRY.

Praktikum des anorganischen Chemikers. Von Dr. Emil Knoevenagel. Pp. viii + 332. (Leipzig: Veit and Co., 1901.) Mk. 7.80.

THE fact that this book emanates from the Heidelberg Laboratory and is dedicated to the memory of the great teacher who first gave that laboratory its fame is calculated to enlist the expectant attention of a critic. The book purports to be an introduction to inorganic chemistry on an experimental basis, and the object is to associate the directions for practical work with adequate theoretical explanations of the phenomena involved. It is, in fact, a blend of preparations, qualitative analyses, quantitative experiments and theoretical chemistry. The plan of the work as a whole is hardly describable, but some idea of its detail may be gathered from the beginning. The student is told to weigh out four grammes of caustic soda, dissolve it in water and make up to 50 c.c. Then, parenthetically, he is asked to calculate the content of caustic soda per litre, to express this in gramme molecules and to say what is the normality. The student is next told the solubility of caustic soda at 15° and 100°, and also informed that the density can be used to measure the concentration. The boiling points of solutions of various concentrations are given. The solution is now to be tested with litmus and turmeric and also to be tasted. Caustic soda is affirmed to be a strong base. A piece is to be left exposed to the air; it is said to deliquesce and also to absorb carbon dioxide, a property of all strong bases. A piece is to be heated in an ignition tube, when t may be seen to melt. We now pass to the heading "Sodium Chloride, NaCl." Some of the caustic soda solution is to be neutralised with hydrochloric acid. Sodium chloride is said to be formed and the student is to write the equation and to make calculations as to the concentration and normality of the HCl solution. The solution of sodium chloride is evaporated until it crystallises, and the process is also observed under the microscope. The salt is tasted, some put into the flame and some treated with sulphuric acid. The next preparation is that of hydrochloric acid in quantity. The solution of the gas in water is to be examined on the same lines as the caustic soda solution. Some dilute acid and then some strong acid are to be heated in a test-tube, and the student is informed what variations of concentration have occurred. Then follows a disquisition on acids, bases and salts.

Space will not permit of further description of the course in detail. After the discussion of acids, bases and salts, we have the tests for hydrochloric acid; sulphuric acid follows, with remarks on its constitutional formula, its action on metals, &c. Nitric acid, hydrogen sulphide, carbonic acid, phosphoric acid and boric acid bring us, for the time being, to the end of the acids. Then come potassium, sodium and ammonium, followed by a discussion of their analytical separation. The rest of the book is much on the same plan. It ends with a chapter on the modern theory of solution (which is not employed in the body of the work) and details of the ordinary analytical separation. Tables of reagents, some density tables and a map of spectra are added.

The impression gained on reading through the book is that we have to do with a genuine attempt to combine accurate practical work with accurate theoretical knowledge. There is a great deal of admirable matter that is not usually to be found in books on practical chemistry. On the other hand, the style of the book is haphazard in the extreme and affords an example of logical detail without logical plan. There is also a constant variation of level in the instruction. A student who calculates the normality of a caustic soda solution and is soon after to have his attention briefly drawn to the possible constitutional formulæ of sulphuric acid is subjected to the indignity of trying the effect of his soda solution on litmus and turmeric paper. Then again, the student is told a great many things that he might easily and profitably establish by experiment, such as the fact that caustic soda exposed to air actually has absorbed carbon dioxide. It is desirable, no doubt, that the student of practical chemistry should understand the behaviour of concentrated and dilute acids on boiling, but the mere statistics of the subject are no explanation, and practical work on the subject should be linked to the simple generalisations that illuminate it.

It would not be right to dwell further on the weaker features of a book which, on the whole, is much more rational and luminous than the great majority of works on practical chemistry. It must be admitted that the task of writing a combined theoretical and practical work on chemistry is very difficult, and that Dr. Knoevenagel has given us a book that well deserves the attention of teachers.

A. S.

OUR BOOK SHELF.

Central Electrical Stations: their Design, Organisation and Management. By C. H. Wordingham. Pp. xvi + 496. (London: C. Griffin and Co., Ltd., 1901.) Price 24*s*. net.

WE venture to think that few, if any, persons could be found better qualified than Mr. Wordingham to write a treatise on central electrical stations, and there can be no question but that he has carried out his task in a very thorough and competent manner in the book before us. Whilst endeavouring to deal with practically every subject which enters into the organisation or management of a central station, the author has wisely given prominence to those matters which are not to be found already in other books. The central station engineer, especially if he have charge of a large generating station such as are now becoming more and more numerous, must be a man of wide experience and attainments, and it would be impossible to compress into one volume all the knowledge that he requires in his profession, quite apart from the consideration that such knowledge cannot be obtained from books alone. But whereas there is plenty of literature already dealing with the separate branches, such as steam engineering, dynamos, &c., there was none, until now, dealing thoroughly with the subject as a whole. Those who have charge of central stations, or those who are ambitious of attaining this distinction, will find Mr. Wordingham's book a very valuable guide.

Central station work has for long attracted a large number of young engineers, the rapid growth due to the spread of electric lighting offering great chances of advancement. It is true, perhaps, that now, as Mr. Wordingham says, the practice is becoming more settled and stereotyped and that entry into this branch of the profession will require a somewhat longer apprenticeship than has been usual hitherto; but this is not likely to discourage many, for the prospects for the future are even brighter than they were in the past. Large electric power schemes and the certain adoption of electric traction for tramways and urban railways point to an expansion which is sure to be both large and rapid for a long time to come. Those who are anxious to take part in this development cannot do better than study the book before us with care and attention. There is a fair amount in the book that is controversial, but this renders it none the less valuable; if the student is not always inclined to agree with the author, he will at least be benefited by the careful consideration of opinions derived from so wide an experience. Some may think, perhaps, that the clerical side of the organisation is given an undue amount of space; this is, however, only in accordance with the scheme of the work, seeing that this is one of those subjects not to be found in other books. Moreover, the student is too prone to think that scientific knowledge alone is sufficient to make a successful engineer and to underrate the importance of a sound and systematic organisation.

Hints to Travellers. Edited by John Coles. 2 vols. Pp. x + 436 and viii + 266. (London: The Royal Geographical Society, 1901.)

THIS useful work, of which the present issue is the eighth edition, has now been divided into two volumes. The first is devoted to the various problems of surveying and practical astronomy, and important additions have been made to the matter brought over from the last edition. The new chapters include a considerable expansion of the article on surveying, ordinary and photographic, a graphic method of predicting the occultation of stars by the moon, and an entire set of tables by the aid of which, and the *Nautical Almanac*, the traveller will have all the materials for computing the results of his observations.

Vol. ii. contains the articles on meteorology, photography, geology, natural history, anthropology, medical hints, &c. Of these, the sections on meteorology and medical items have been entirely re-written and considerably enlarged; the others all revised and brought up to date.

This work has already gained its reputation as a most serviceable and complete guide for almost all classes of travellers, and in its present elaborated form cannot fail to give additional satisfaction.

L'Optique des Rayons de Röntgen et des Rayons secondaires que en dérivent. Par G. Sagnac. Pp. 166. (Paris: Gauthier-Villars, 1900.)

THIS book gives a useful account of some of the properties of the Röntgen rays. The earlier chapters deal with the properties of the primary rays as they issue from the vacuum tube. A valuable feature is the explanation given of the cause of certain spurious effects which have been put forward as proving diffraction of the rays.

The second and larger part of the book deals with the secondary rays which issue from heavy metals when the primary rays from the tube falls on them. M. Sagnac makes it clear that this phenomenon is not properly to be described as a "surface effect." He shows that an element of volume of a heavy metal traversed by the rays gives out secondary radiation equally in all directions. The sudden change of conditions at the surface of the metal is not what is primarily concerned. The heavy metals absorb the primary rays so powerfully, however, that they can only penetrate to a small depth, consequently the secondary radiation does, in fact, come principally from near the neighbourhood of the surface. Many other original observations are described, but though of considerable interest they seem to leave the question of what causes the secondary radiation, and why only heavy metals emit it, almost as far from solution as ever.

R. J. S.

Cerebral Science. Studies in Anatomical Psychology. By Wallace Wood, M.D., Professor of History of Art in the New York University. Pp. xii + 128. (London: Baillière, Tindall and Cox, 1901.)

THE subordinate title of this book alone renders it impossible for us to take it seriously, despite the fact of its being dedicated to the memory of Taine and Broca. The book abounds in platitudes, ejaculations and short dictatorial declarations, with here and there an allusion to the historic, poetic and classic; but all without plan or logical sequence of ideas. The "creation of the human head—the study of the human brain," is defined as "the new science for the opening century," and "characterology" is regarded as the great field through which, by the study of man and the lower animals, there is to be reached the classification of souls. Of these our author would distinguish five classes, and when it is seen that he would locate the "strong" soul in the "parietal regions," the "good" in the "metopic chambers" and the "beautiful" in those of the "summit," we deem further comment needless, except to remark that the author is indeed amusing.

The Humane Review. Vol. i. April, 1900, to January 1901. Pp. 384. (London: Ernest Bell, 1901.)

WITH a few of the contributions to this volume, men of science and other observers of nature will find themselves in sympathy. Mr. W. H. Hudson pleads for the preservation of the furze wren or Dartford warbler, and other rare birds, and criticises the feather fashion; Prof. J. Howard Moore writes on the psychical kinship of man and the other animals; Mr. H. R. Fox Bourne states the claims of uncivilised races; M. Elisée Reclus champions vegetarianism; and Mr. Bernard Shaw makes amusing and characteristic remarks upon the alleged conflict between science and common sense.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The National Anti-Vivisection Society and Lord Lister.

I HAVE read your attack upon me in your issue of May 16.

In your comments on the anti-vivisection meeting at St. James's Hall you say that I "discoursed inaccurately on Lord Lister's scientific work." I did nothing of the kind, I never made any allusions whatever to his scientific work. You next say with respect to the fifty-eight vivisectors for whom Lord Lister signed certificates exempting them from the use of anæsthetics that "the probability is that personally he was not acquainted with half-a-dozen of the licensees." This is to bring a graver charge against Lord Lister than anybody has yet formulated, for the signature of Lord Lister is the evidence offered the public in the parliamentary report that the vivisectors in question are individually known to Lord Lister to be persons who will not inflict needless cruelties upon animals. I preferred to assume that they were all his intimate friends than to suppose that he had signed such certificates merely because he was asked to do so.

You are quite right in saying that I did not tell the audience that the vast majority of experiments under these certificates are mere "pin pricks." If I had done so I should have been misleading it. Inoculations may begin with a pin prick, but they commonly involve much subsequent suffering.

You next complain of my statement that "the more hospitals connected themselves with vivisection the larger was the grant per bed they might expect to receive from the Prince of Wales's Fund." It is simply waste of time to abuse me for making that statement till you can disprove it. I have given the figures and you will find them in the audited accounts of the hospitals.

Your account of what passed between my Society and the Poplar Hospital is inaccurate, and "the reply of this institution" cited by you is not to be found in the correspondence which has been published and which you should have read before affecting to quote from it.

Lastly, what we have suggested to the heads of the religious bodies in the matter of Hospital Sunday is, that if the offertories are to be handed into the general funds of hospitals from which same general funds schools licensed for vivisection are subsidised, the congregations should be informed from the pulpits that their money is not exclusively intended for the tending of the sick, but will in part be diverted to the education of medical students and to the support of vivisectional laboratories.

May I ask what is your objection to such a course being pursued?

I do not mind your attacking me in your paper personally by name—I have entered this controversy intending to give and expecting to receive good blows—but I have myself been scrupulous to make no statement that is not supported by unimpeachable authority, and I have a right to expect that a responsible paper such as yours should exercise a similar exactitude if it joins in the controversy and takes upon itself to allude to any statement of mine as "scurrilous."

STEPHEN COLERIDGE.

The National Anti-Vivisection Society, London, S.W., May 21.

[(1) Mr. Coleridge is reported to have stated that Lord Lister's experiment consisted in passing a needle and thread through the eyeball of a rabbit and leaving the thread there. The needle and thread were passed through a special part of the skin of the eye only (cornea). The object of the experiment would have been entirely frustrated if the needle and thread had been passed through the eye. The question to be answered was whether inflammation could be caused by irritation of non-vascular tissues. Speaking of Lord Lister's experiment as he did, showed that Mr. Coleridge not only did not take the trouble to get accurate fact with regard to the experiment, but also was totally ignorant of its object.

(2) The inference to be drawn from Mr. Coleridge's remark that Lord Lister was the "intimate friend" of fifty-eight vivisectors is that the signing of the respective licensees, exempting from the use of anæsthetics, was of the nature of a "job." This remark was obviously "scurrilous." Lord Lister signed

these certificates as President of the Royal Society; he knew the licensees to be fit persons to have the respective licenses, but there was no question of individual intimate friendship.

(3) The occurrence of pain after inoculation experiments is relatively very rare, and to refer to these experiments to a popular audience as vivisections is certainly misleading it, and Mr. Coleridge must have known this. The statement that the majority of these so-called vivisections were mere pin-pricks is true.

(4) We do not complain of Mr. Coleridge's statement of what he terms the "diversion" of hospital funds to the corresponding medical schools, but we simply say that the allotment of the Prince of Wales's Hospital Fund was not influenced in any way by whether a hospital had laboratories or so-called vivisectors attached to it or not. We regard the statement that Lord Lister wilfully diverted public funds to endow vivisection as scurrilous. We entirely deny that hospital funds are, by being used for the support of medical schools, "diverted," in Mr. Coleridge's sense, from the patients. Medical schools are essential to large hospitals, and any grant made to them out of hospital funds is only in return for services rendered, although it indirectly helps the progress of medical science.

(5) The statement that Mr. Coleridge tried to make a bargain with a London hospital concerning the appointment of its staff and that the hospital declined is true; the mere wording of the reply is a matter of no importance. If Mr. Coleridge will publish the correspondence to which he refers we shall be prepared to consider it exhaustively.

(6) We entirely object to the relation between hospitals and medical schools being put before the public subscribers to the Hospital Sunday Fund in the way Mr. Coleridge suggests. If Mr. Coleridge has any scheme by which the large hospitals can receive the services of the medical profession more cheaply than they do at present he is quite justified in putting this before the public. He is, however, not justified in stigmatising grants made to medical schools as being "diverted" from the use of the sick.—EDITOR.]

Vitrified Quartz.

A STUDY of the viscous properties of vitrified quartz in which I was engaged last year, and which I communicated to the Geological Congress of 1900, revealed a degree of plasticity and molecular instability which I think justify Mr. Shenstone's reserve in pronouncing on the applicability of this substance to thermometry at high temperatures (NATURE, May 16). A few of the measurements I obtained may be of interest. I may observe that the method of observation was to stretch a quartz fibre (as supplied by the Cambridge Instrument Co.) in a horizontal platinum tube, which is heated by a current and clamped in the meldometer, its temperature being determined in terms of its thermal expansion. The fibre, which passes axially through the tube, is fixed at one extremity, and at the other is attached to a light pendulum, the mass of which can be increased, and which it deflects from the vertical. It is observed by two micrometers placed at some few centimetres to either extremity of the tube, so that any slip in its fixed attachment will be detected. The tube is 10 cm. in length and ·2 cm. in diameter. Tensions are calculated in kilos. per square centimetre, and rate of elongation in centimetres per minute per unit of tension per centimetre of fibre. The different fibres used are designated *a*, *b*, *c*, &c.

Fibre	Temperature	Duration of observation in minutes	Tension	Rate of stretch per unit of tension
a	715°	270	638	$0·23 + 10^{-8}$
b	735°	95	1350	0·16 ,,
b	785°	165	,,	0·66 ,,
c	870°	150	82·2	1·3 ,,
c	915°	60	27·4	5·3 ,,
c	,,	50	54·8	4·4 ,,
c	920°	60	82·2	6·2 ,,
d	915°	10	422	6·6 ,,
e	940°	10	320	8·5 ,,
f	1040°	10	,,	35·9 ,,

This table is abridged from one giving fuller details. The fibres varied greatly in diameter and possibly somewhat in their viscous properties, but the results are all one way—an increasing yield with increasing temperature and a rate of stretch approximately proportional to the applied force. But this last assertion cannot go without some reservation. At the higher temperatures, the rate of elongation was observed to diminish steadily when the observations were much prolonged. Ultimately the fibre generally breaks. When observed now between crossed nicols the fibre is found to be partially crystallised, the crystallisation extending inwards from the surface. This crystallised layer is sometimes cracked and peeled from the core beneath, the result, probably, of the very great volume-change attendant on crystallisation. The gradual diminution in rate of stretch, and a certain degree of irregularity in the results at higher temperatures, may well be due to this molecular alteration.

So far as can be inferred from the observations, the results are due to plasticity, complicated at higher temperatures by gradual crystallisation. Nor is there anything, so far as I can gather, in the least opposed to this view contained in Prof. Callendar's interesting experiments on the thermal expansion of vitreous quartz.

It will be seen from the experiments I have quoted that the viscous stretch at the lower temperatures is small in amount. With prolonged use, however, and if any considerable difference between internal and external pressure existed, thermometers would be affected by it sufficiently to necessitate frequent re-adjustment of fixed points. I find, for example, as the result of a rough estimation, that with an excess of pressure of one atmosphere within, a spherical bulb 1 cm. in diameter and ¼ mm. thick in the walls would, at 785° C., increase in volume by 0·1 per cent. in about 83 hours. At 870° C. this increase will occur in about 40 hours. At 920° C. the same increase in volume would occur in about 8 hours if the contraction due to crystallisation, which the experiments lead us to expect, did not act the other way. The final result, after 8 hours' heating at 920° C., would be impossible to predict.

I have more recently found that vitrified quartz, reduced to powder and exposed over a Bunsen for 35 days in a closed unglazed porcelain crucible at a temperature just under the melting-point of gold (1066°) loses its sharp edges, rounding every point and angle, and simultaneously develops incipient crystallisation, which appears in the form of radial spherulitic structures, often with anisotropic centres. J. JOLY.

Geological laboratory, Trinity College, Dublin.

Statistical Investigations on Variability and Heredity.

EARLIER appeals in your columns have met with such friendly response from scattered workers that I venture again to trouble you with an appeal for aid. I have three investigations in progress wherein help would be very welcome:—

(1) The measurement of physical and intellectual characters in pairs of brothers or sisters. Upwards of 1400 have now been observed and measured, but I have still not sufficient data. Village schools usually present a great deal of measurable material, but it is difficult to reach their teachers except through individual approach. Any of your readers who can interest their local teachers in observing and measuring pairs of children will do me a great service, and I shall be glad to send papers of instruction and a head-spanner for their use.

In examining carefully the data from nearly thirty primary schools recently returned to me, I only found two cases in which the teacher had not been fully able to use the spanner to advantage. Of course I shall be equally pleased to send papers and head-spanners to masters or mistresses in secondary schools.

(2) I shall be glad of any number of orange-tip male butterflies. They must have been caught wild and not bred, and I should like contributions from as many districts as possible. The specimens need not be very carefully set, and if the upper wings are not badly damaged they will be sure to be of use.

(3) Clutches of blackbirds' or thrushes' eggs. Each clutch must be kept perfectly separate, and certainly be from one bird. They are better unblown. If blown the hole or holes must not be at the ends. As some of your readers may have clutches they wish to preserve, but would not mind the risk of lending, I will return those so desired.

Contributions desired under (2) and (3) are for determining the intensity of homotyposis, a factor, I believe, to be at the basis of all hereditary resemblance. KARL PEARSON.

University College, London, W.C., May 25.

Prehistoric Implements in the Transvaal and Orange River Colony.

THE reason for writing these short notes is the desire to point out to those with the requisite knowledge the places where what are probably palæolithic remains can be found in South Africa. I am not able to dilate on the technical side of the question, having only a smattering of the subject.

Being a volunteer in the British Army, the immense distances covered by us gave one an opportunity of seeing a larger tract of country than would be possible as a civilian. Unfortunately, in South Africa the amount of systematic research into the subject of prehistoric weapons has been but small, and I think the Orange River Colony and the Transvaal would be found very rich in all such remains. The heavy rains and nature of the country allow many glimpses of the geological formations, and the dongas and dry river banks will nearly always reveal some old "drift." The nature of our marching did not allow us to go far from the beaten road, but a few worked stones could be picked up in every day's march.

Starting at Sterkstroom, with the 3rd Division, such specimens can be found all round the town of about 2 inches in length in a fair state of preservation, some few showing the effect of being water-worn. At a coal mine named Wallsend, the hill where we camped is simply covered with scrapers and chips; in fact I collected quite a dozen in the small circle covered by our bell tent. Further north, at Bethulie Bridge, they are lying in the subsoil of the river bank, as well as in the stony reaches of the river. Springfontein, Smithfield, Dewetsdorp, in fact right up to Bloemfontein, the country is covered with stones all about the same size, roughly chipped and, in all probability, of palæolithic origin. They are of the leaf form and vary from 1 to 2½ inches in length.

At the Vaal River they were more water-worn and larger, about 5 by 2 inches. Better specimens could probably be obtained by examining the drift, which I myself had no opportunity of doing. I found only two or three specimens round about Pretoria. Middleburg and Belfast were the last two places I was in, and in the former an immense quantity of implements can be picked up in the river bed and in the subsoil adjoining. They are of the large size, as those in the Vaal River, some which I found being about 5 by 5 inches and quite 1 inch thick.

Unfortunately, Army regulations as to the weight of kit had to be carried out, and I had three separate times to throw my collection away. I had kept the best specimens and ticketed them, but in the end I found myself discharged from the Army as a time-expired volunteer in Cape Town, with only three or four dilapidated specimens from Belfast.

If regulars and volunteers would write about their observations of other parts of the country covered by them it would indicate at a glance the richest places where a systematic research could be undertaken with the best possible results.

Sunderland. STANLEY B. HUTT.

The Age of the Woburn Abbey Musk-Ox.

IN the notice of the young musk-ox at Woburn Abbey which appeared in NATURE of May 16 it was stated that the animal was considerably more than two years of age when the photograph was taken. This age was assigned on account of a statement made by Dr. Allen in his recent memoir on the Greenland and American musk-oxen that the Woburn specimens must have been yearlings when they were first photographed in 1899. His reason for making that statement were that a young calf captured at Fort Conder in May, 1899, had a black face, instead of the white-spotted faces of the Woburn animals; and that the latter had consequently changed their coats. Now the Woburn specimens were captured on Clavering Island on August 16 of that year, and from information that has recently been supplied to me it seems almost certain that they were calves of that year, probably born the preceding April or May. If this be so, and if calves have black faces when first born, it would seem that the Woburn specimens had already changed their first coats when shipped for England during the late summer, a photograph of them having been taken on board ship showing the white faces. It thus appears that when the photograph reproduced in NATURE was taken, the animal was not more than two years old, and possibly rather less. R. LYDEKKER.

The Subjective Lowering of Pitch.

As a general rule, the pitch of a musical note does not in any way depend upon its intensity, but solely upon the wave-length. It appears probable, however, that any wave motion of very great intensity produces distorted effects. Thus we find that a very loud sound may so affect the ear of the observer as to appear flatter than it really is. This is a purely subjective effect.

Dr. Burton was, I believe, the first to investigate the phenomenon, and some of his results (together with his explanation of them) will be found in vol. xiii. of the *Proceedings* of the Physical Society. My own attention was first drawn to the matter by observing what appeared to be the false intonation of certain singers upon loud notes, either when I was conducting near those singers or when I was rehearsing in a small room. Reading then of Dr. Burton's researches, I was led to investigate them for myself.

The subjective lowering of pitch is an undoubted fact, *i.e.* a very loud note does appear flatter than it really is.

If a C tuning-fork (middle C, 256 vibrations per second) be *strongly* bowed, and then be quickly brought near the ear, before its loud note has had time to die away, the sound will appear flattened to about $B\flat_1$, or even A_1, the amount of the effect being different to different ears.

It is more difficult to obtain the effect with higher forks; indeed, a C^1 fork (512) must be bowed very strongly indeed to give the effect at all. An E fork (320) appears to give a flat $D\sharp$, and a G fork (384) gives $F\sharp$.

The effect is a subjective one, caused by great intensity, for it vanishes as the sound gets softer, and can then be restored by bringing the fork nearer the ear, thus again increasing the intensity. In this last case the restoration of effect is sudden, and is not due to any gradual movement of the fork (Doppler's principle).

If the position of the source of sound be fixed, the subjective note gets sharper as the intensity of the vibrations gets less; for instance, an E fork (320), when very strongly bowed, gave $C\sharp$ as its subjective note; but, as the vibrations died down, this $C\sharp$ varied to D, then became $E\flat$, and finally and suddenly stopped altogether.

The amount of the subjective effect differs with different individuals, both in pitch and in intensity. What to one person appears a flattening of a minor 3rd, to another auditor appears a flattening of only a major 2nd, but in every case it appears to be a flattening and not a sharpening. Also the loudness of the subjective note appears different, even to the different ears of the same person.

In the case of some organ-pipes tested, the following results were obtained:—

C pipe (open, 256) gave A_1 as subjective.
E pipe (open, 320) gave D as subjective.
G pipe (open, 384) gave $F\sharp$ as subjective.
C^1 pipe (open, 512) gave B as subjective.

If an ear-trumpet be used, a very loud source of sound is not necessary in order to obtain subjective effects. If the source of sound be placed at a distance just great enough to prevent subjective flattening, and then an ear-trumpet be used, the subjective note at once appears.

Much of my own musical work has been done amongst male voices, and I have frequently noticed that a singer of good concert-room power may, if practising in a small room, seemingly sing with flat intonation. I should be glad to have further experience concerning this from your contributors, who will also, I hope, have noticed the effect in the case of brass instruments.

E. HURREN HARDING.

Normal College, Bangor, May 15.

RECENT STUDIES OF OLD ITALIAN VOLCANOES.

THE abundant and well-preserved extinct volcanoes of Italy have long had a great fascination for students of geology. So many allusions to them are scattered through the literature of the science, and so many accounts of them, more or less brief, have been furnished by those who have visited them, that their general characters and the more important varieties of their rocks are now tolerably familiar. But until lately hardly any of them have been subjected to that minute dissection which modern vulcanology and petrography now demand. The Italian geologists, however, have at last taken up the investigation in considerable detail, and are issuing excellent maps and monographs of different volcanic districts, which well deserve the careful attention of all who take an interest in the progress of volcanic geology. To some of the latest of these publications a brief reference may here be made.

The Italian Geological Survey has entered upon the study of the volcanoes of Central Italy and their products, and as a commencement has issued a detailed account of that remarkable volcanic centre which forms the group of the Alban Hills to the east of Rome. This work has been accomplished by one of the staff, Mr. V. Sabatini, who has long been known for his geological enthusiasm.[1] It forms a volume of nearly 400 pages, with an excellent map of the region, ten plates of views and petrographical sections and 79 figures inserted in the text. After a brief introduction devoted to a discussion of some of the theoretical principles involved in the interpretation of volcanic phenomena, the author proceeds to give a sketch of the topography of the region and of the position of its several eruptive vents. He recognises, as at Vesuvius, the records of two great periods in the volcanic history. The first, one of conspicuous vigour, which built up a large cone that was finally demolished by a stupendous explosion; the second, one of minor force, whereby a cone was formed within the original circuit. Each of these phases has been attended with the production of secondary or adventitious cones, and the author endeavours to trace a series of lines of fissure along which, in his opinion, these cones have been produced. It is to be noted that some of his lines appear to rest merely on the evidence of carbonated or sulphurous springs, and even where they run from cone to cone some effort of imagination is needed to picture the lines of fissure as he gives them. In Southern Italy the geologists are less fanciful in dealing with the unseen substructure of their volcanoes.

The second chapter treats of the various hypotheses which have been proposed in explanation of the origin of the Roman Campagna and the Alban Hills, and especially of the tuffs so widely developed in that region. A detailed description of these tuffs is given; they are classified as lithoid, homogeneous, granular, pumiceous and earthy, and reference is made to the terrestrial flora and fauna enclosed in them. Their plants include many familiar living species. On Monte Celio, land-shells were found; on Monte Verde, the molluscs were of fresh-water species; in the tuffs between Nettuno and Astura, Meli has collected a considerable number of marine and estuarine forms, while a large assemblage of bryozoans has been gathered from the volcanic tuffs of Anzio and Nettuno. The succession of the different varieties of tuff is next given as displayed in many sections in and around Rome, and an attempt is made to estimate the cubic contents of the vast sheet of tuff which has been discharged from the Vulcano Laziale.

The third chapter deals with the nature and classification of the Latian lavas. These are grouped into normal leucitites and leucotephrites. The alterations which they have suffered are described, such as the transformation of leucite into felspar. Detailed descriptions are then given, in chapters iv. and v., of the rocks of each important part of the outer and inner cones of the volcano, and the author, following a practice for which he no doubt can cite high authority, adopts a somewhat complicated and cumbrous system of symbols to express the petrographical characters of each rock. Such a system may be convenient, especially where rapid comparisons of different species and varieties of rocks are desired by a student who has taken the time and labour necessary to understand it and commit it to memory. But life is too short and geological literature is too long for such a task on the part of ordinary readers. It would not have cost much more type to have accompanied the symbols with a brief statement of the composition of the rocks in plain language. The origin and constitution of the craters of Nemi, Castel Gandolfo and Ariccia take up the next three chapters. The author here, as in the rest of the volume, deals less fully with the tectonic than with the petrographical part of his subject. He would have added much to the geological interest of his memoir had he given more ample details of the structure of the great volcano and presented a clear and vivid outline of the whole succession of volcanic phenomena of which it preserves the record. Perhaps he may intend to deal with these parts of his subject in a subsequent treatise. A useful bibliography is appended to the volume. It is much to be desired, however, that precise references had always been given to the passages in the works of the authors whose names are cited in the text. The continuation of the important research of which Mr. Sabatini gives here the first instalment will be awaited with much interest.

In Southern Italy the investigation of volcanic phenomena is naturally incited by the irresistible attractions of the active volcanoes of that region. The study of the extinct cones and craters, however, has perhaps rather been retarded by the abundant opportunities offered there of witnessing the actual progress of eruptions. Within the last few years the subject of the older volcanoes has been taken up by several observers, who, without the resources of the National Survey to assist them, have nevertheless been successful in bringing much fresh information to light. Two of these geologists—Prof. G. de Lorenzo, of the University of Naples, and Prof. C. Riva, of the University of Pavia—deserve especial commendation for the enthusiasm of their researches. The volume just issued of the *Transactions* of the Royal Academy of Naples contains two detailed memoirs, one by Prof. G. de Lorenzo on the well-known Monte Vulture between Naples and the Adriatic, the other by the two authors conjointly on the seldom-visited crater-island of Vivàra between the islands of Ischia and Procida in the Bay of Naples.[1]

The memoir on Monte Vulture extends to 207 closely printed quarto pages, and is illustrated by numerous figures in the text as well as a map and a number of excellent plates in photogravure, of which one is here reproduced. In an introduction, the history of observation regarding this ancient volcano is briefly sketched. The author then proceeds to describe the various sedimentary series through which the volcanic explosions took place. These consist of Trias, Cretaceous, Eocene and Miocene formations, together with Pliocene and Pleistocene deposits both marine and terrestrial. The stratigraphical relations of these various groups of strata had already been discussed by M. de Lorenzo in a paper on the geology of the Southern Apennines, published in 1896, and they are well displayed in a plate of sections accompanying the present monograph. The incomplete series of Mesozoic formations is shown to have been considerably disturbed before Tertiary time, while the Eocene and Miocene deposits had likewise been plicated and denuded before the Pliocene strata were laid down upon them. In the southern outskirts of the mountain the volcanic pile rests on the younger Tertiary groups, while towards the north it spreads over the area of the Eocene and Miocene "Flysch." The faulted nature of the

[1] I vulcani dell' Italia Centrale e i loro Prodotti. Parte Prima—Vulcano Laziale, di V. Sabatini. Roma, 1900. (R. Ufficio Geologico. Memorie Descrittive della Carta Geologica d' Italia, vol. x.). This volume, the author informs us, is based on the work of 112 days in the field and the examination of 400 microscopic slides of rocks. The volcanic centre here referred to under the name of "Vulcano Laziale" comprises the Monti Laziali and the Monti Albani and their surroundings.

[1] "Atti della Reale Accademia delle Scienze Fisische e Matematiche di Napoli," second series, vol. x. 1901.

ground is well shown in some of the illustrations, but the author does not believe that Monte Vulture has had its site determined by the stupendous linear fracture which some theorists have imagined to extend eastwards from Vesuvius. He has satisfied himself, by a study of the geological structure of the surrounding country, that no trace of any such dominant dislocation exists.

The various rocks of the volcanic pile are then described in some detail. They are shown to form a numerous and continuous series of varieties between the two extreme limits of trachytoid phonolites, on the one hand, and basalts on the other. The principal types of lava are thus arranged: Hauyne-phonolite, anorthoclase-phonolite, hauyne-tephrite, leuco-hauyne-tephrite, leuco-hauyne-basanite, leucitic basalt, leucitite, nephelinite, hauynophyre. Each of these types is fully described and is illustrated by excellent plates of its microscopic structure. A section is devoted to the characters of the agglomerates by which the lavas are accompanied, and another to the inclusions contained both in the lavas and the fragmental materials, some of which were doubtless derived from the underlying sedimentary platform, others probably represent portions of the subterranean magma which have acquired a granitoid structure at a great depth, while in some cases their origin is doubtful.

Having described the materials of the volcanic pile the author next furnishes an account of the way in which they have been built up into the huge mass of Monte Vulture. In a long and interesting section of the paper the structure and probable history of the mountain are discussed, and the position of its various rocks and some of the successive phases in the evolution of the topography are explained in diagrams inserted in the text. The next division treats of the lakes which, partly in consequence of the volcanic disturbances, were formed in some number and of considerable size during Pleistocene time. This subject had already been treated by M. de Lorenzo in a separate memoir (*Atti Accad. Scien. Napoli*, 1898) in which he had shown that Southern Italy in Quaternary time was dotted over with large and small basins of fresh water. Whether formed in consequence of changes in the topography produced by the volcanic eruptions or existing before these eruptions began, the lakes around Monte Vulture were more or less filled up with limno-volcanic tuffs containing fresh-water shells and likewise remains of *Elephas antiquus*, *Hippopotamus major*, *Ursus spelaeus*, *Felis spelaea*, *Hyena spelaea* and *Cervus elephas*.

In a final section the author states what he believes to be the bearing of the history of Monte Vulture on theoretical questions of volcanism. He insists on the total independence of the eruptions of this centre, which he thinks had no direct communication with those of any other. He can find no trace of the great connecting fissures which have been supposed to link together all the old and modern volcanoes of Southern Italy. He regards the eruptions of this centre as having begun long after the great orogenic movements that gave rise to the Apennine chain, and at a time when perennial snows and glaciers still lingered on the surrounding heights. Phonolitic lavas first made their appearance, followed by tephrites, basanites and basalts, which form the great mass of the mountain. Two peripheral vents can be distinguished, one anterior, the other posterior to the formation of the great central cone. The last stupendous manifestation of volcanic energy seems to have been the explosion which blew out the great crater in which the two crater-lakes of Monticchio now lie (Fig. 1).

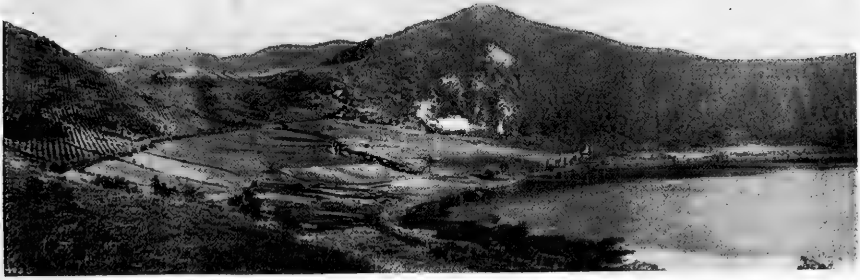

FIG. 1.—View of the interior of Monte Vulture, showing the great exterior rampart and the crater lakes of Monticchio.

M. de Lorenzo acknowledges the important services rendered to him by his friend Prof. Riva—the young and accomplished mineralogist of Pavia whose petrographical assistance and photographic skill were freely given in the preparation of this important monograph. The other memoir above cited is a joint production of the two observers. It is entitled "Il Cratere di Vivàra nelle Isole Flegree," and forms No. 8 in the same volume of the *Transactions* of the Naples Academy. It begins with an interesting historical introduction and then at once enters on a discussion of the rocks of which the remarkable island is composed. These consist entirely of fragmentary materials which have been heaped up around a crater, as in the other volcanic cones of the Campi Phlegræi. A careful account is first given of the coarse breccias or agglomerates, which include blocks of trachytic obsidian, sanidinites with quartz and catoforite, anorthoclase-trachytes with ægirine, augitic trachytes, mica-trachytes, andesitic trachytes, basalts, trachydolerites, rocks of dioritic type (monzonites) and other varieties. Full petrographical descriptions of these rocks, together with micro-photographs of their internal structure, are given. The varieties of pumice, lapilli and tuff are likewise detailed. It is shown that the eruptions of Vivàra, unlike those of the neighbouring region, did not consist solely of trachytic material, but discharged an admixture of a trachytic and a basaltic magma, so as to have heaped up a rich assortment of the most remarkable rocks, beginning with a quartziferous sanidinite and passing through various trachytic types to normal olivine-basalt. The relations of these rocks to the other similar materials in the Phlegræan region are next discussed, and the authors then pass to the structure of the island, which they show to consist of successive sheets or banks of ejected fragmentary volcanic material without any accompanying lavas, and disposed in the usual divergent arrangement, the portions on the outer surface of the cone dipping steeply outwards into the sea, while those on the inside are inclined towards the centre of the crater. Vivàra rises out of the Mediterranean as a truncated cone which attains a height of 109 metres and a diameter across its upper rim of about 900 metres. The eastern half of the cone has been broken down and the sea now fills the circular crater. The waves and rains have cut many sections of the rocks, and thus the structure of the old volcano has been admirably dissected. All students of vulcanology will welcome these memoirs and hope that they may be regarded as the precursors of a long series in which the volcanic history of Southern Italy will be thoroughly elucidated. ARCH. GEIKIE.

AGRICULTURE IN NEW SOUTH WALES.

THE *Agricultural Gazette* of New South Wales has ushered in the century, and, at the same time, marked the consummation of an Australian Commonwealth, by issuing a special federal edition. The history of the agricultural development of the Colony is dealt within most interesting fashion by the chief inspector of agriculture, Mr. W. S. Campbell, who, in the hundred and thirteen pages that he appropriates, unfolds a fascinating tale of the early struggles and final success of this offspring of Great Britain, whose birth dates from the year 1788.

In the section devoted to chemistry in relation to agriculture a considerable feature is made of the value to the agriculturist of soil-analysis. Expert advice in the treatment of soils is said to be much sought after by the farmers of New South Wales, and a typical report on a poor soil is inserted with the view of showing the form that the information takes. The results of the physical and chemical tests are first tabulated, and from these the soil specialist formulates the following recommendations:—"This is a very sour soil, low in plant-food, and only moderately supplied with humus. Its retentive power for water is low, consequently its power of resisting drought. It will not give the best results till sweetened and brought into good condition. The treatment recommended is, first, liming at the rate of about one ton per acre. This will sweeten the soil, and supply lime in which the soil is deficient. Then a quick-growing crop, such as vetches, lupins, cow-pea, &c., should be grown and ploughed under when just maturing. This will supply vegetable matter, improve the texture, and supply nitrogen, in all of which essentials the soil is weak. After this treatment the soil should be able, with proper manuring, to grow any of the ordinary fruits suitable to the district, such as are mentioned in your letter. Peaches and stone fruit should do very well, as well as any vegetables. With regard to the most suitable manuring, this should be on the lines recommended in the attached departmental pamphlet, 'Formulæ for Fertilisers,' which gives the manuring required for the different crops in average soil. In your case the quantities recommended may be somewhat increased. I would particularly impress upon you, (1) That this report is intended to be merely suggestive, and must be followed up by careful experiments on your own part; (2) . . . . (3) That you should impart to your neighbours any information you may gain from this report as freely as it is given to you; (4) That you should communicate regularly with the Department as to the results of your experiments, for we have special facilities for advising you as to the best manures for your special needs, and the cheapest form in which you can get the same."

This typical report is reprinted almost in full in order to show what the Department of Agriculture of New South Wales professes to be able to do in one section of the farmer's business, namely, the management of his soil. Experience in other countries has shown that advice given in the light of laboratory tests on soil is apt to be rather uncertain in its results, but in Australia science has, in this respect, it is said, been very useful to farmers. The practice of liming in that country seems to vary considerably from what holds in England. Where sourness in soil is the trouble an English farmer would consider a dressing of five tons of lime per acre none too much, but in New South Wales one ton is recommended as the maximum dose, to be repeated, if need be, a few years later.

Not the least interesting section of this federal number is that which treats of agricultural education. Technical instruction in agriculture appears to be eminently practical, and it is noted with satisfaction "that among the large number of young people so trained there are to be found so great a proportion who have achieved signal success upon farms and orchards of their own." The curriculum at the Hawkesbury College is almost rigorous in its thoroughness. The students who are on dairy duty turn out at 4.15 a.m., and are probably ready for their breakfast, which is served at seven. The sixty-five horses and mules that cultivate the College farm of 1100 acres demand the attention of another "gang" of students, whose day's work does not close till 8 p.m. Hard manual work does not appear to discourage the young farmer of New South Wales in his pursuit of knowledge, the present accommodation of the College being inadequate to meet the demands for admission. Some illustrations of the practical character of the education are culled from the interesting volume before us, which reflects a colonial vitality most gratifying to the mother-country.

CLIMATE AND TIME AND MARS.

THE astronomical theory of an Ice Age, of which the foundation is attributed to Adhémar, has been the subject of much discussion. Its laborious exposition by Dr. Croll has been justly considered a work of great merit, but it may be said to have proved more interesting as a speculation than convincing as an argument. The adequacy of the theory to explain all that is required of it is a highly controversial matter, and was debated with no little heat in the columns of this journal in 1895-6. Consequently it is desirable to state that this note is written from the point of view of qualified belief in the argument as expounded by Sir R. Ball.

The contribution of astronomy to the data of the problem can be very easily stated. Let us consider the northern hemisphere of a planet, the eccentricity of whose orbit, e, is sensible, but so small that only its first power need be taken into account. In the first place the ratio of the total solar radiation received in summer and winter is $1+a : 1-a$, where $a = 2 \sin \omega/\pi$, ω being the obliquity of the equator to the orbit. This is the law discovered by Wiener, and in the case of the earth $a = \cdot 25$. The ratio of the duration of summer and winter, *i.e.* of the periods between the equinoxes, is $1+b : 1-b$, where $b = 4e \sin \lambda/\pi$, λ being the true anomaly of the spring equinox. Hence the ratio of the mean heat received in a given time in summer and winter is $(1+a)/(1+b) : (1-a)/(1-b)$. In the southern hemisphere the corresponding ratio is $(1+a)/(1-b) : (1-a)/(1+b)$. At the present time $b = \cdot 02$, but in circumstances which would cause the earth's eccentricity to reach its maximum value (about $\cdot 0747$), $b = \cdot 09$ when $\lambda = 90°$. Under such conditions, then, the southern winter would undoubtedly be more severe than at present, while the northern winter would be to some extent mitigated. Precession would have the effect of causing this state of things to alternate in the two hemispheres. The argument is perfectly simple and definite, and can only be questioned on the score of degree, not of fact. It thus passes from the domain of astronomy to that of meteorology. Here the ground is very debatable, and Mr. Culverwell's discussion of the solar radiation incident on individual zones of the earth may be regarded as a decided contribution to a study of this part of the question. But his researches do not seem to be necessarily so conclusive against the astronomical theory of an Ice Age as this author supposes. For the present purpose, however, enough has been said as to the application of the theory to our own planet.

The conditions which hold in the case of Mars resemble in a remarkable manner those which hold in the case of the earth, except in one particular. The eccentricity is ·0933, and hence $b = \cdot 11$. The constant $a = \cdot 27$. These values of a and b apparently afford an excellent example of the conditions required by the theory for a glacial epoch in the southern hemisphere of Mars. It would be illogical to compare the state of corresponding regions on the earth and on Mars, because the concomitant circumstances cannot be expected to be the same. But it is reasonable to suppose that in corresponding seasons the latter planet should show different phenomena in the two hemispheres. As an index of these variations we naturally look to the polar caps, the size of which is known to vary greatly with the seasons. The results to be expected are of this kind:

Hemisphere.	Season.	Duration.	Climate.	Size of Cap.
N	Summer	Long	Cool	Min.
N	Winter	Short	Mild	Lesser Max.
S	Summer	Short	Hot	Min.
S	Winter	Long	Cold	Greater Max.

The amount of heat during summer in either case being the same, there is room for question as to the relative size of the two minima. But it seems clear that the radiation incident on the southern hemisphere will be transformed into heat at a higher temperature than in the northern. According to the laws of thermodynamics it should, therefore, be more effective in the south. The total energy received is the same, but the available energy is greater. Or the matter may be considered differently. It is quite conceivable that during the long cool summer the temperature would not rise above the melting point of ice or whatever substance is in question, while it would be otherwise during the short hot summer. An approach to this condition would lead us to expect the more pronounced minimum in the southern hemisphere.

To compare the suggestions of theory with the facts of observation, we can turn to a recent paper on the subject by Mr. Lowell.[1] He concludes that the caps are composed of ice and not carbonic acid, on account of the difficulty of obtaining the latter substance in a liquid form, a state which he considers proved by observation to exist on Mars. He expresses a belief that the Martian sky is cloudless during the day and that the surface of the planet is protected by cloud at night. It must be confessed that the regularity of transition at sunrise and sunset from one condition to the other almost surpasses our belief and tends to discredit the deductions from the study of projections upon the terminator. Mr. Lowell then considers the evidence of the polar caps. The result is to confirm the expectations formed above, and the conclusion is perhaps the more convincing because the writer seems to find the phenomena surprising. And this point is rather important, for the evidence as to the maxima is not so complete as could be desired. It is to be hoped that Mr. Lowell's examination of this part of the question will lead to the acquisition of more complete and satisfactory evidence.

With regard to the minima, Mr. Lowell does not give the simple explanation suggested above, but attributes the phenomena observed to a deficiency of precipitation. In fact, he professes to prove that "as the precipitation increases a time must come when the southern minimum will actually exceed the northern one in size, *and do so more and more, indefinitely*." As no physical principle is invoked to account for this result, it would seem to be based on assumption. Examination shows that the assumptions tacitly involved are (1) that the maximum of each cap is increased in the *same* ratio, (2) that the amount melted at each cap remains exactly the same as before. It would then follow that in each hemisphere the rate of proportionate growth of the minimum would exceed that of the maximum. We now introduce the observed fact that the ratio of maximum to minimum is greater in the southern hemisphere. This, added to the foregoing, is necessary and sufficient to prove that the rate of proportionate growth of the minimum is greater in the southern than in the northern hemisphere. But the observed fact employed might equally well have been stated in this form: comparing the southern with the northern hemisphere, the ratio of the minima does not exceed the ratio of the maxima; and by assumption (1) the latter is constant. Hence, even on the assumptions the words italicised in the above quotation do not appear justified. The southern minimum may tend towards a relative increase, but there is a limit to the increase. The general idea is perhaps suggestive, but the second assumption involved must be considered highly improbable, and without it the whole theory fails.

At the end of the paper Mr. Lowell turns his attention to the eccentric position of the southern cap. He declines to believe that this well-known peculiarity is due to local elevation, but, on the contrary, attributes it to a region of depression, where the cap has acquired an exceptional thickness. The phenomenon is a very curious one, but speculation as to its origin has probably not much value.

[1] "Mars on Glacial Epochs," by Percival Lowell: *Proceedings* of the American Philosophical Society, Nov. 16, 1900.

THE TELAUTOGRAPH.

IN an article on "Electric Signalling" which appeared recently in these columns (vol. lxiv, p. 6) we referred to the writing telegraph invented by Mr. Foster Ritchie. We have since had an opportunity of examining the instrument and seeing it at work, and are enabled to give a full description of it. The problem of devising an apparatus which should telegraphically transmit the actual handwriting or drawing of the person sending the message is one which has attracted a number of inventors. The difficulties to be overcome are, however, numerous, and in consequence up to the present no really satisfactory instrument has been invented. These difficulties seem to have been mastered in Mr. Ritchie's telautograph in a very ingenious manner, and the instrument is one which should prove thoroughly trustworthy and serviceable. Although it is not to be expected that the telautograph will replace ordinary telegraphic apparatus to any very marked extent, seeing that the speed of signalling is necessarily limited, yet there are numerous cases in which it should be of use. To give only one example, there are many persons possessing private telephone lines who would gladly supplement them with an instrument of this kind by which written instructions can be sent whether there is any one present to receive them or not. Other cases of like kind will doubtless occur to the reader.

One of the chief merits of the Ritchie telautograph lies in the fact that only two wires are needed to connect the transmitting and receiving instruments; these are connected as a single loop earthed at each end, thus providing three distinct circuits since currents can be sent through either of the two wires to return by earth or can be sent through one wire to return by the other. The general principles of the apparatus will be understood from Figs. 1 and 2. Fig. 1 is from a photograph of the instrument with the cover and paper removed in order to show the working parts. It will be seen from this photograph that the complete apparatus consists both of a transmitting instrument, fixed on the horizontal baseboard, and a receiving instrument, supported on the four upright pillars. Fig. 2 is a diagram of the connections, only the principal connections being shown in order to avoid a multiplicity of lines.

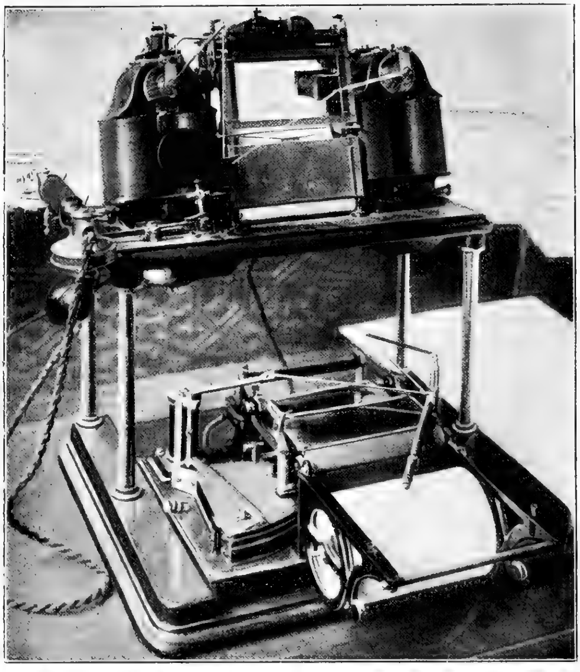

FIG. 1.—General view of the Telautograph.

When the operator wishes to send a message he takes up the transmitting pencil, A, and with the point shifts to the left the catch C. This operation actuates a grip which shifts the paper forward at both ends of the line, thus bringing up a clean piece to write upon, and also connects up the transmitting and disconnects the receiving apparatus at the home end. At the same time, it reverses the connections of one of the sets of batteries, two sets of which are used, one at each end of the line, which are normally connected in opposition so that when the connections of one set are reversed by shifting the catch C they are connected in series. The operator now proceeds to write on the transmitting paper: the pencil, A, is connected to two sets of levers, LL, which actuate the sliding contacts of two rheostats, RR′; these rheostats are connected one in series with each of the two lines, R in the line EWWE′, and R′ in the line EW′W′E′. As the resistances of the rheostats are varied by the motion of the sliding contacts corresponding to the motion of the pencil, A, the currents in the two lines will vary. These currents pass through and deflect the moving coils of two galvanometers of the d'Arsonval type, G, G′, in the receiving instrument; these coils are connected by two sets of levers, L′L′, to the receiving pen, B. It will thus be seen that the position of the pen B is controlled by the deflections of the two galvanometers, which are in their turn dependent on the position of the transmitting pencil A: the pen will therefore exactly follow in its motions the movements of the pencil and will consequently repeat on the paper at the receiving end the drawing made on that at the transmitting end. The currents, after traversing the coils of G and G′, pass through the relays D and D′ (the use of which will be explained presently) and then return by earth.

From what has been said so far it is obvious that the receiving pen will copy the movements of the pencil A, whether the pencil is being used to write on the paper or merely being moved about above it. It is necessary to prevent the pen B from making marks on the paper except when A is actually writing on the paper at the transmitting end. This is effected in the following ingenious manner. A small induction coil at the transmitting end has its primary circuit, P, completed through a contact, M, attached to the desk on which the writing paper rests: the terminals of the secondary coil, S, are connected to the line wires, W,W′, and the circuit is completed at the receiving end through the relay H and the condenser K′. Intermittent currents are thus sent round the circuit SWHW′S and, actuating the relay H, put in action a pen lifting magnet (not shown in the diagram) which raises the bar F and holds the pen B off the paper. When the operator starts writing the pressure on the paper breaks the contact at M and thus stops the vibratory currents; the relay H is released and the bar F falls back, thus allowing the pen to come into contact with the receiving paper. It will be noticed that the vibratory currents are superimposed on the ordinary line currents, but they are prevented from affecting the receiving pen by the self-induction of the galvanometer circuit, whilst at the same time the line currents are prevented from passing through the relay H by the condensers K and K′. A small amount of the intermittent current does pass through the galvanometer coils, but this is, as a matter of fact, advantageous, as it prevents, by the slight vibration it produces, any tendency to sticking.

When the writer has filled up the strip of paper he again shifts the clutch C and this moves forward the paper at his end and also, through the operation of the relay D, shifts that at the receiving end. At the same time the pen B returns to the ink bath and takes a fresh supply of ink: the ink bath is not shown in Fig. 2, but can be seen, with the pen resting in it, in Fig. 1 in front of the

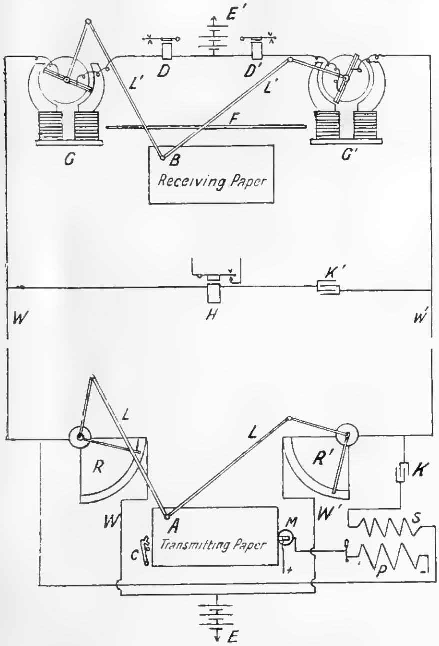

FIG. 2.—Diagram of telautograph connections.

galvanometer on the left. The pen, which is shaped like a small pipe, the bowl being a reservoir for the ink, holds sufficient ink to cover the amount of paper exposed at one time. The relay D′ controls a local bell circuit and is used for ringing up. Neither the connections of this bell circuit nor of the paper shifting magnet are shown in Fig. 2, the relays only being shown in order to avoid unnecessary complication.

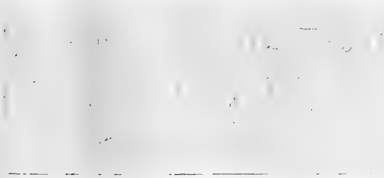

FIG. 3.—Transmitted message.

A specimen of the writing transmitted by the telautograph is shown in Figs. 3 and 4. Fig. 3 shows the words as written in pencil at the transmitting end, and Fig. 4 as received at the far end. These words were transmitted over an artificial line nearly 300 miles long; it will be seen that although the writing is somewhat distorted it does not lose its character and is indeed a very fair reproduction. The words were written on the first telautograph that Mr. Ritchie has constructed; in future instruments it is to be expected that the reproduction will be even more accurate, as several improvements in detail have been introduced, but it must be admitted that the performance of the present apparatus leaves little to be desired. There is no difficulty in writing, in spite of the pencil being attached to the rheostats and having to move

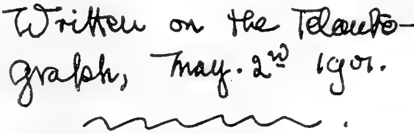

FIG. 4—Received message.

them; everything seems to move very freely and it is almost as easy to write as with an ordinary pen. Moreover, as long as the paper is not shifted, the writer can go back and make alterations and additions with perfect accuracy.

We are much indebted to the Telautograph Co. for allowing us to examine the instrument, and to Mr. Foster Ritchie for very kindly explaining to us the details of its construction.

NOTES.

MR. BALFOUR has often pleaded for the increase of facilities for scientific research, and has pointed out how, in this respect, our country compares unfavourably with some others. The festival dinner of the Medical Graduates' College and Polyclinic, on May 22, gave him another opportunity to remind the public of existing deficiencies and the duties of wealthy citizens towards them. As purely scientific research can never be self-supporting, and as, moreover, every addition to knowledge is of value, it has peculiar claims upon the public and the nation. How small, comparatively, is the response to these claims is known to all of us. Here science is tolerated but it cannot be said to be encouraged; and this because the people who have the means to further scientific interests are not in sympathy with them. The State leaves the adequate provision for scientific research to private benevolence, but liberal benefactions are few and far between, so work which would be done here if means were available is left to other nations. Many men of science spend their private incomes to carry on investigations which elsewhere would be afforded generous support, and they often have to leave work unfinished because such assistance is not forthcoming. "I do not believe," said Mr. Balfour, "that any man who looks round the equipment of our universities or medical schools, or other places of education, can honestly say in his heart that we have done enough to equip research with all the costly armoury which research must have in these modern days. We, the richest country in the world, lag behind Germany, France, Switzerland, and Italy. Is it not disgraceful? Are we too poor or are we too stupid? Do we lack the imagination required to show what these apparently remote and abstract studies do for the happiness of mankind? We can appreciate that which obviously and directly ministers to human advancement and facility, but seem, somehow or another, to be deficient in that higher form of imagination, in that longer sight, which sees in studies which have no obvious, necessary or immediate result the foundation of the knowledge which shall give far greater happiness to mankind than any immediate, material, industrial advancement can possibly do; and I fear, and greatly fear, that, lacking th imagination, we have allowed ourselves to lag in the glorious race run now by civilised countries in pursuit of knowledge, and we have permitted ourselves to far too large an extent to depend upon others for those additions to our knowledge which surely we might have made for ourselves." Unfortunately there seems little hope of improvement in this depressing condition of affairs. We would ask, however, how comes it that the members of the Government, knowing the position of things and expressing belief in the salvation of the nation through science, neglects to take up the responsibilities which are overlooked by private benefactors? If we have to look to private sources for the provision for scientific research furnished by the State in other countries, the outlook is not encouraging to contemplate. We lag behind other nations now; and, applying the natural law to the political world, steady progress in the growth of scientific knowledge will only be possible when the conditions for development are made more favourable than they are at present.

THE annual visitation of the Royal Observatory, Greenwich, will be held on Saturday, June 1.

AT the annual meeting of the Institution of Electrical Engineers to be held this evening, an illuminated address received from the American Institute of Electrical Engineers will be presented. The address has been sent as an expression of thanks for courtesies extended to members of the American Institute during their visit to London last year, and in connection with the joint meeting at Paris. It is a pleasant token of the cordial relationship existing between British and American electrical engineers, and the feeling which prompted the resolutions embodied in the address will doubtless be much appreciated.

THE success of the visit of members of the Institution of Electrical Engineers to Switzerland in 1899 has led to arrangements being made for a visit to Germany next month. There will be three parties, one visiting Berlin only, another visiting Berlin and Dresden, and a third visiting Berlin, Dresden, Nüremberg, Frankfurt-a-Main and other places. The whole party will leave London on Saturday, June 22, and upon their arrival at Hanover on Sunday evening will be entertained at dinner by the town authorities. At Berlin, in addition to visits to works, a visit will be paid to the Technical High School, where Prof. Slaby will show the college to the members. Several dinners and receptions will be given to the visitors in Berlin and elsewhere by electro-technical societies and other bodies. Ladies may accompany the members, and the visit promises to be pleasant and profitable to all who take part in it.

As may well be imagined from the wealth of blossoms now to be seen in our gardens, the flowers exhibited at the Temple Show of the Royal Horticultural Society last week were very fine. Those, however, who looked for novelties met, for the most part, with disappointment. There was nothing of startling popular interest or of extraordinary scientific significance, while new garden plants were not very notable and seemed few and far between. Mr. H. J. Elwes, F.R.S., showed *Cypripedium guttàta* in bloom, a plant which he obtained a year or two ago on the Altai Mountains. Its habitat was in a dense forest that was almost impenetrable. The markings on the perianth were of a very pleasing red, and the specimens did credit to their treatment, which included their being kept on ice during the winter. The series of insectivorous plants hard by, sent by Mr. A. J. Bruce, of Chorlton-cum-Hardy, was very fine, and the Sarracenias may be particularly mentioned. One flippant visitor likened the leaves of some to steamboat ventilators which had been twisted. A similar collection belonging to Mr. R. R. J. Measures was also worthy of careful examination. Very suggestive of the balance that must be maintained between roots and foliage were the trees artificially dwarfed by the Japanese. These were quite plentiful, being exhibited by professional and amateur horticulturists alike. Here the skilful grower has so limited the root system and so cunningly reduced the number of leaves that, practically speaking, only sufficient food is manufactured to maintain the plant in health, there being hardly any surplus to provide the material necessary if growth is to continue. It does continue, but so slowly that we may not get a tree more than two feet high after three hundred years have passed over its head.

IN recent years there has been much progress in the processes of preparing sulphur for use in the prevention of diseases of plants, and the demand, in consequence, has greatly increased. The methods actually employed for estimating the quality of these preparations are, however, now out of date and leave much to be desired, especially as regards the mixtures of sulphur and copper sulphate. With the view to encourage special studies on this subject, the Federation of the Agricultural Unions of Italy, together with the Agricultural Unions of Padua and Florence, has therefore decided to open an International Prize Competition for the sum of 1000 francs in gold, to be awarded to the person who discovers and makes public the best method for obtaining exact and trustworthy results in the determination of the quality of flowers of sulphur and of mixtures of sulphur and copper sulphate. Competitors must send in their papers in a sealed envelope to the head office of the Federation (Ufficio direttivo della Federazione italiana dei Consorzi agrari, Piacenza, Italy) before March 1, 1902. The papers will be examined by a special commission to be named by the Reale Accademia dei Lincei, Rome.

ALL those who knew Mr. Anthony Wilkin will regret to learn that he died of dysentery in Cairo, in the twenty-fourth year of his age, on May 17. In his early undergraduate days Wilkin published a bright little book, "On the Nile with a Camera," and while still an undergraduate he accompanied the Cambridge Anthropological Expedition to Torres Straits and New Guinea. His historical and sociological studies in Cambridge prepared him for the investigations he made on the land tenure, laws of inheritance and other social questions. He also made notes on the various kinds of habitations in the districts he visited. All these observations will be duly published in the Reports of the Expedition. Immediately after his first winter's digging in Egypt with Prof. Flinders Petrie, he went with Mr. D. Randall-Maciver to Algeria to study the problem of the supposed relationship, actual or cultural, of the Berbers with the ancient Egyptians. An interesting exhibition of the objects then collected was displayed at the Anthropological Institute in the summer, and later on in the year Wilkin published a well-written and richly illustrated popular account of their experiences entitled "Among the Berbers of Algeria." Quite recently the scientific results were published in a sumptuously illustrated joint work entitled "Lybian Notes." Mr. Wilkin was an enthusiastic traveller and was projecting important schemes for future work. There is little doubt that had he lived he would have distinguished himself as a thoroughly trained field-ethnologist and scientific explorer.

THE National Home-Reading Union has arranged to hold a summer meeting at Winchester on June 22–29, when lectures will be given on various aspects of King Alfred, whose millenary will be celebrated this year. In connection with the meeting, Mr. J. E. Marr, F.R.S., will give four lectures on "The Application of Geology to Scenery," a secondary purpose of the meeting being the study of the geology and botany of the district as well as its archæology.

THE Simla correspondent of the *Times* reports that the Secretary of State has sanctioned a scheme for an ethnographical survey of British India in accordance with the suggestions made in 1900 by the British Association. The work will be done by civil officers in addition to their own duties, Mr. Risley being appointed director of ethnography. The annual expenditure will be 40,000 rupees, and the total cost is estimated at 1½ lakhs, excluding the cost of printing. The Government hope that ethnologists and scientific societies in Europe and America will assist the director with advice, refer to him the points they desire to make the subject of inquiry in India, and supply him with copies of publications bearing on the researches about to be undertaken during the next four years.

THE third series of trials of motor vehicles for heavy traffic is arranged to take place in Liverpool and neighbourhood during the five days commencing Monday, June 3. Referring to the results of previous trials, the *Times* points out that in 1898 the wheels of the four competing vehicles proved structurally defective when subjected to the hammering action of granite sets and cobble sets, whilst minor troubles arose in respect to adhesion and with the condensers, &c. The second trials, which took place in 1899, provided satisfactory evidence that the tire and adhesion difficulties had been overcome, for none of the wheels gave the smallest trouble, and five out of six of the competing vehicles in the hill-climbing tests successfully surmounted gradients varying between one in nine and one in thirteen with as heavy a load as six and a half tons. Yet the judges found that the strength of these vehicles was "below what is compatible with a satisfactory life in commercial work"—a state of things which they attributed mainly to "the difficulties imposed by meeting the limit of three tons tare under the Locomotives on Highways Act, 1896." In order to see whether manufacturers could improve their designs so as to produce an efficient commercial vehicle under the three-ton limit of tare, the Liverpool Self-propelled Traffic Association has allowed an interval of two years between the second trials and the third series now about to be held. For the coming trials an entry of thirteen vehicles has been secured, which will compete in four classes. Class A is for comparatively light vehicles propelled by internal combustion engines using deodorised naphtha or petroleum spirit, and carrying a load of only one and a half tons. The vehicles entered under the other three classes are all steam propelled, electricity being again unrepresented. The steam waggons, however, comprise a great variety of design, including several boilers of the flash, or instantaneous generation, type.

THE Report of the Council of the Royal Agricultural Society of England, read at the annual meeting on Wednesday of last week, was not an altogether satisfactory one. The total number of governors and members is more than ten thousand, but since last year there has been a nominal reduction of 633—which includes 314 voluntary resignations. A few of these have withdrawn from the Society on account of the decision of the Council to discontinue the annual migratory shows after 1902, because of the serious losses the last three have involved. The show this year will be held at Cardiff, from June 26 to July 1, and in 1902 the last of the series will be held at Carlisle. These migratory shows will be superseded by a permanent showyard at Twyford Abbey—a few miles out of London. For the prizes of 40*l.* and 20*l.*, offered by the Society for portable oil engines, eight entries have been received, the trials of which will take place in the Cardiff showyard in the week previous to the show. For the similar prizes offered for agricultural locomotive engines, no entry has been received; and for the prize of 15*l.* offered by the Society for the best small ice-making plant suitable for a dairy, only one entry has been made. The council report that at the Woburn Experimental Farm the feeding experiments have shown that sheep fatten perfectly well, and without any drawbacks, when fed on mangels instead of swedes. Gorse has been proved to be a useful food, but the results were slightly inferior to those obtained by the use of hay. Progress is being made with the usual field experiments and with the investigations of various agricultural problems, including the eradication of farm weeds. At the pot-culture station experiments are being continued in connection with Hills' bequest. Much attention has been given to the value of seeds, and reports have been supplied to members of the Society in regard to the purity and germination of 116 samples of different seeds. A disease in the cherry orchards of Kent, which has seriously affected the cherry crop, has been investigated by the Society's consulting botanist, and a description and figures of the disease have been printed as a leaflet and extensively circulated in Kent and other fruit-growing districts. The Zoological Department has been chiefly concerned during the past six months with pests injurious to stored produce and with such insects as are troublesome all the year round. Some of the more important applications have had reference to forestry, and advice has been given with regard to various insects attacking plantations of coniferous and other trees.

A DISASTROUS explosion occurred at the Universal Colliery, situated at the top of Aber Valley, a few miles from Caerphilly, on Friday last, no less than eighty-three men having perished through the accident. Mr. Dyer Lewis, assistant inspector of mines, is reported by the *Times* to have said that there was no longer any doubt that the explosion was caused by coal dust, adding that the long continuance of the north-east wind, which practically prevailed for three weeks, might probably have had the effect of drying up the air passing through the workings and thus have caused the coal dust to become drier.

WE understand that the Admiralty is proceeding energetically with the fitting of wireless telegraphy to the ships of the British Navy. The "Apps-Newton" coil has been adopted as the standard pattern, and a large number of coils and transmitters have been ordered.

A COMPLETE installation of Marconi's wireless telegraphy specially suitable for signalling purposes as used in the Navy has been fitted on board the Elder, Dempster Beaver liner *Lake Champlain*. This installation is the first which has been fitted on any of the Atlantic liners sailing from Liverpool. The *Lake Champlain* left the Mersey for Halifax last Tuesday with more than 1000 passengers, and arrangements were made to establish communication between the vessel and the Marconi wireless telegraph station at Holyhead. The *Times* states that at 9.37 p.m., when off the Skerries, communication was obtained with the Holyhead station, the vessel being then thirteen miles distant. Numerous telegrams were then forwarded from passengers to friends in all parts of the United Kingdom, each message being acknowledged by the receiving operator. Constant communication with the station was continued until 1 a.m., the vessel being then thirty-seven miles distant. Communication was established with the Marconi station at Rosslare, and at 4.30 a.m. a fresh batch of telegrams was forwarded, notifying the vessel's arrival off the Tuskar light to the owners, Messrs. Elder, Dempster and Co. The position of the ship was nineteen miles from Rosslare telegraph station. The last telegram was forwarded at 7.30 a.m., at a distance of nearly thirty miles from Rosslare.

OUR paragraph directing attention to the proposal to erect a memorial to the late Right Hon. Prof. Huxley in Ealing has elicited one noteworthy response. The contributor, who gives neither name nor address, begins his covering letter: "In the current issue of NATURE" (which presumably he had seen at a free library) "the reader is informed of a movement on foot in Ealing for a memorial to the memory of Huxley. With gladness I hasten to contribute my mite," and concludes an able, if lengthy, epistle as follows: "I enclose a postal order for 1*s.*

as some *little* help towards the memorial. Even now I am giving beyond my means, as I am merely a casual dock labourer, living from hand to mouth, and often hardly able to make both ends meet. But I never let my mind get rusty, and from my boyhood have had a keen partiality for 'Nature's leading lights' and their works. Among the brightest of these, and of whom any nation might be justly proud, flashes out Thomas Henry Huxley."

THE *Procès-verbaux* of the meeting of the International Committee of Weights and Measures at Paris in September last have been received. The Committee had under their consideration the reports of the director on the work of their bureau for 1899-1900, by which reports it would appear that besides the ordinary verification work of the bureau (standard metres, kilograms and thermometers for various Governments, Universities and scientific authorities) important researches have been carried out as to alloys of nickel and steel (Dr. Guillaume); as to comparisons of platinum and hydrogen thermometers (Dr. Chappuis and Dr. Harker), and the determination of the mass of a cubic-decimetre of distilled water. Dr. Benoit reports that the latter mass may be taken as equivalent to 999·936 grammes; but it does not appear that the true value of a cubic-inch of water is to be derived from the cubic-decimetre. The best ordinary alloy for measures of length (as bars, line-measures, survey ribands, &c.) appears from Dr. Benoit's report to be one of 64·3 per cent. of steel and 35·7 per cent. of nickel.

We note that the Committee referred to in the foregoing note propose to take up the vexed question of an international series of sizes of screw-threads, based on the millimetre. The annual expenditure of the Committee amounts at present to 75,000 francs, but it would appear that at the general conference to be held at Paris in October next, under the Metric Convention 1875, a proposal is to be made to raise the annual budget to 100,000 francs, at which sum it was formerly fixed, so as to meet necessary expenditure on the instrumental equipment and maintenance of the bureau. Towards this annual expenditure each High Contracting State contributes a sum based on its population, and on the extent to which the metric system may be in force within each country; Great Britain contributes about 5000 francs. Some effort appears to have been made in September last by the Decimal Association (London) to induce the Committee to lay before the French Government a proposition to invite the attention of the Governments of Great Britain, Russia and the United States to the desirability of making the metric system compulsory in these countries; but the Committee do not appear to have approached the French Government on this delicate proposition. From the communications addressed to the Committee by Prof. A. Michelson (Chicago), Mr. Chaney and Prof. Mendeléeff, it seems that the metric system is, however, making way in the three great countries above mentioned.

Die Umschau contains a short account of Hoffmann's model flying-machine. The peculiarity of this model (which weighs 3½ kilogrammes) is that it is supported on three long legs, by the aid of which it runs on wheels on a track or on the ground till it has gained sufficient velocity to rise in the air, when the legs fold up automatically and the model flies somewhat after the manner of a stork. It is claimed that such an arrangement applied to a man-lifting machine would obviate the difficulties connected with the starting and landing.

WE have received a copy of the magnetical, meteorological and seismological observations made at the Government Observatory, Bombay, for the years 1898 and 1899, under the direction of Mr. N. A. F. Moos, which extends the record of this important series to a period of fifty-four years. The observatory is very completely equipped both with ordinary and self-recording instruments, the standards being read five times daily, commencing with 6h. a.m. A Dines' pressure tube anemometer, probably the most satisfactory instrument for recording the varying strength of the gust of wind, was erected in February 1897, and a Milne's seismograph in September 1898. In addition to the tables of results obtained from the automatic instruments and from the direct eye observations, the volume contains the following valuable appendices:—(*a*) Hourly means of the magnetic elements, as determined from quiet days, for the years 1894-9; (*b*) Notes on the harmonic analysis of temperature and pressure for 1876-1895, with plates; (*c*) Hourly and daily normals of the several meteorological elements, and their variations expressed by Bessel's formula.

WE have received from Mr. J. Baxendell, meteorologist to the Southport Corporation, the report and results of observations at the Fernley Observatory and allied stations for the year 1900. With a small amount of means at their disposal, Mr. Baxendell and his staff perform a large amount of very useful work, much of it of an experimental kind, in addition to the routine work of a well-equipped observatory. Special attention is given to the results of various anemometers of the most modern construction, and it is stated that the highest pressure yet recorded by a pressure plate anemometer is 20·7 lbs. per square foot. Another useful investigation is the comparison between the amounts of bright sunshine recorded by the Campbell-Stokes and the Jordan sunshine recorders. The monthly percentages of three years show that the latter instrument records somewhat higher values, except in the winter months. The falling off at this period appears to be traceable to increased relative humidity and to greater prevalence of fog. The report contains useful tables of rainfall and sunshine values at a considerable number of stations—mostly sea-side resorts.

THE third sheet of the North Atlantic and Mediterranean Pilot Charts published by the Meteorological Council is devoted to the month of June. Being the midsummer month, the atmospheric conditions are usually of the quietest description, the region in which the gale frequency exceeds 10 per cent. being now limited to the far north, beyond the 55th parallel. Disturbances of a cyclonic character are, however, of frequent occurrence on the more frequented shipping routes, but as most of them are of slight intensity severe gales seldom result. At this season, the conditions begin to assume a less steady appearance in the doldrums off the African coast, developing later into conditions which give birth to hurricanes moving westward towards the West Indies. Similar local features of the winds on the American coasts and in the Mediterranean are dealt with. Fog is very frequent, above 50 per cent., from the coast of Maine eastward across the Newfoundland Banks, and even the 10 per cent. frequency extends, with only a narrow break in about 20° W., from Sandy Hook to the Severn and the Bay of Biscay. Fogs as dense and as wet as those of the Banks now visit the Straits of Gibraltar, but, fortunately, they last only a few hours. With the exception of a berg and some field ice sighted on March 16 last, there has been no report of ice at sea this year, though at various times the pack in some of the Newfoundland and Cape Breton bays has been driven out by high winds. The eastward drift of the Gulf Stream, which the May chart showed was interrupted in 47° N. 27° W., continues across the ocean to our south-western shores in June, there being a good deal of easterly and north-easterly current in the space between Ireland and the north-west of Spain. The equatorial counter-current of the doldrums is met with as a prevailing set as far west as the 42nd meridian; the equatorial west-going current attains a high velocity, 60 to 85 miles a day; and in Florida Strait the Gulf Stream may reach 100 miles in a day. In every way the June chart is as interesting and valuable as its predecessors.

WE have received from Messrs. Friedländer the second part of their valuable *International Zoologist's Directory*, containing the emendations and additions necessary to bring the issue of 1895 up to date. These emendations include a list of zoologists deceased since that date, as well as a record of all changes of address that could be ascertained. The lists of the staffs of all the more important zoological institutes and museums form a feature of this part; and, so far as we have been able to test it, the work is comprehensive and singularly free from errors.

THE only original article in the May issue of the *Zoologist* is a continuation of Mr. E. Selous' observations on the habits of the great crested grebe. The author expended a vast amount of time and trouble in watching a pair of these beautiful birds during the breeding season. Attention is drawn to the circumstance that the male bird takes a considerable share in the duties of incubation; and it is suggested that it likewise constructs a platform for its own use in the neighbourhood of the nest. This leads the author to formulate a theory as to the origin of the "runs" of the Australian bower-birds, which, in opposition to the views of other naturalists, he regards as specially modified nests.

DR. A. APPELLÖF sends us the first fasciculus of a new work under his editorship, entitled "Meeresfauna von Bergen," now in course of publication by the Bergen Museum. The systematic investigation of the marine fauna of Bergen was commenced many years ago, and since the establishment there of a marine biological station has advanced with great rapidity. Many interesting problems are connected with the fauna of the sea of this district, which is now to be described in considerable detail. The work will include a map showing the different faunal zones and dredging stations. In the present fasciculus Mr. K. Bonnevie, of Christiania, treats of the hydroid polyps, Dr. R. Hartmeyer of the holosomatous ascidians, and Mr. E. Arnesen of the calcareous sponges. The first two subjects are illustrated with plates or figures, and the names of the authors afford a sufficient guarantee of the manner in which each is treated.

WE have received numbers 6 and 7 of the Liverpool Marine Biological Committee's *Memoirs*, both of which maintain the high level of their predecessors. The first of these, by Mr. A. Scott, is devoted to the fish-parasites of the genera Lepeophtheirus and Lernæa. These crustacean (copepod) parasites are almost wholly restricted to portions of the fish they infest which are in direct communication with the exterior, such as the skin itself, the fins, mouth, gill-chamber and gills, nostrils, or even the eye. The full life-history of both the types mentioned is given in considerable detail; and it is shown that while in the former development takes the form of steady progression, in the latter it assumes an equally marked degradation. Indeed, so strange are the phases assumed by Lernæa (as is well shown in the plates with which the memoir is illustrated), that there is little wonder that the older naturalists, when its life-history was still unknown, were puzzled as to its serial position, and failed to recognise its near kinship to the other genus described in the present fasciculus. The second of the two *Memoirs*, by Mr. R. C. Punnett, deals with the genus Lineus, as exemplified by that common British nemertean worm, *L. gesserensis*, notable, if for no other reason, on account of having, in its different phases, received no less than ten generic and thirteen specific titles. Varying between 6 and 20 centimetres in length, and displaying two distinct colour phases, this worm occurs abundantly underneath stones between tide-marks and also in the laminarian zone, frequently occurring in tangled masses. Its distribution is also large, extending from Greenland to Madeira on one side of the Atlantic and to Florida on the other. In addition to a careful and well-illustrated description of its anatomy and life-history, Mr. Punnett furnishes his readers with an elaborate table, showing at a glance the exact systematic position of this curious worm.

THE Summary Report of the Geological Survey of Canada for 1900 has a melancholy interest for geologists owing to the recent death of Dr. G. M. Dawson, the Director. It is a clearly printed work of 203 pages, with a colour-printed map of the Atlin gold-fields, and its price is ten cents. As usual, while due attention is given to the scientific work the practical subjects are treated as exhaustively as possible, and general observations on natural history are included. So many different topics are discussed that it is impossible to give any condensed account of them; suffice it to say that the Yukon district with its gold and coal workings, the coal of British Columbia and Nova Scotia, the lakes of Ontario and New Brunswick, the finding of natural gas in borings in the valley of the Nation river, the anorthosite of Quebec, and numerous other matters are dealt with.

WE have received from Messrs. Merck a pamphlet upon "Tannoform," an antiseptic which has lately been very much employed in veterinary practice. This substance was first prepared about six years ago, and is a condensation product of tannic acid and formaldehyde, its composition being represented by the formula $CH_2\langle {C_{14}H_9O_9 \atop C_{14}H_9O_9}$. Tannoform is a buff-coloured powder and is odourless and almost tasteless. It is insoluble in water, but fairly soluble in alcohol and ether, also in caustic alkalis and ammonia. Formaldehyde is one of the most powerful antiseptics and germicides which we have, but being at the same time a strong irritant it can only be used in very dilute solutions. Tannoform appears to possess all the antiseptic properties of formaldehyde, but is free from its unpleasant smell and irritating action, beside which the well-known astringent properties of tannic acid are also retained. Owing to its anhydrodic action, this substance was at first chiefly employed as a remedy for excessive perspiration of the feet and other parts of the body. Tannoform appears to have been first employed for veterinary purposes in the veterinary college of Berlin, when it was found that, not only could it be employed in place of the unpleasant smelling and expensive iodoform, but that wounds treated with it healed more rapidly than when iodoform was used. In cases of purulent and malodorous wounds, tannoform is said to be very beneficial, because of its antiseptic and deodorising properties. When taken internally, this substance appears to be quite harmless, even when large doses are administered. It has been found of special value in cases of diarrhœa and intestinal catarrh. Most antiseptics carry with them an odour—not usually pleasant—by means of which their presence can be detected. In tannoform we have an odourless and powerful antiseptic.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. T. J. Erroll; a Guinea Baboon (*Cynocephalus sphinx* ♂) from Africa, presented by Mr. C. W. Fowke; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Lord Hindlip; a Guilding's Amazon (*Chrysotis guildingi*) from St. Vincent, presented by the Earl of Crawford and Balcarres; a Woolly Opossum (*Didelphys lanigera*) from Colombia, a Violet-necked Lory (*Eos ricinata*) from Moluccas, a Razor-billed Curassow (*Mitua tuberosa*) from Guiana, deposited; a Demoiselle Crane (*Anthropoides virgo*) from North Africa, two Summer Ducks (*Æx sponsa* ♂ ♂) from North America, two Mandarin Ducks (*Æx galericulata* ♂ ♀) from China, an African Elephant (*Elephas africanus* ♂) from Abyssinia, purchased; a Duke of Bedford's Deer (*Cervus xanthopygius* ♀) a Japanese Deer (*Cervus sika* ♂) a Thar (*Hemitragus jemlaicus* ♂) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JUNE.

June 3. 14h. 4m. to 15h. 13m. Moon occults μ Sagittarii (mag. 4·1).
3. 15h. 6m. to 16h. 12m. Moon occults 15 Sagittarii (mag. 5·6).
4. 9h. Jupiter in conjunction with moon, Jupiter 3° 53′ S.
4. 14h. 49m. to 15h. 59m. Moon occults B.A.C. 6536 (mag. 5·5).
4. 17h. Saturn in conjunction with moon. Saturn 3° 43′ S.
5. 20h. Uranus in opposition to the sun.
7. 0h. Mercury in conjunction with ϵ Geminorum, star 4′ N.
7. 14h. 59m. to 15h. 54m. Moon occults c^1 Capricorni (mag. 5·2).
14. Saturn. Outer minor axis of the outer ring = 17″·58.
15. Venus. Illuminated portion of disc = 0·977, Mars = 0·890
15. 17h. Mercury at greatest elongation, E. 24° 39′.
24. 12h. 2m. Minimum of Algol (β Persei).
25. 7h. 57m. to 9h. 18m. Moon occults B.A.C. 4531 (mag. 5·7).
27. 8h. 51m. Minimum of Algol (β Persei).
28. 9h. 47m. to 11h. 54m. Transit of Jupiter's Sat. IV.
28. 11h. 15m. to 12h. 15m. Moon occults ω^1 Scorpii (mag. 4·1).
28. 11h. 30m. to 12h. 48m. Moon occults ω^2 Scorpii (mag. 4·6).
30. 5h. Jupiter in opposition to the sun.
30. 10h. 4m. to 12h. 21m. Transit of Jupiter's Sat. I. The satellite will be almost centrally superposed on its own shadow.

THE RECENT TOTAL ECLIPSE OF THE SUN.—A further telegram from the *Times* correspondent at Sawahloento, dated May 23 gives a few more particulars respecting the results obtained by the various observers occupying the stations in or near Sumatra. The weather is described as having been moderately good at all these stations—best at Fort de Koch, worst at Solok—thin clouds were present at most of them.

In all eleven camps were formed, comprising one Dutch, two English, four American, one Russian, one French, one Jesuit and one Japanese. Generally partial success is reported from most of the camps, the unfortunate exception being that of Prof. Barnard, who had set up a most elaborate collection of instruments at Solok, the chief being a telescope of 61 feet focal length, with which he hoped to obtain photographs of the corona on plates 40 inches square. Three of the plates show only feeble fragments of the brighter portions of the coronal structure.

It is reported that good photographs of the *flash* spectrum were obtained here, and no names being mentioned we can only surmise that this refers to the spectroscopic party from the Yerkes and United States observatories, who were furnished with powerful spectrographs and established their camp at Fort de Koch, near by, so as to be approximately on the northern edge of the moon's shadow. Mr. Jewell had charge of a number of gratings of large size, both plane and concave, provided with films 36 inches long, intending to pay special attention to the ultra-violet regions of the chromospheric spectrum. Dr. Humphreys also took spectrographic apparatus. Prof. Skinner, in charge of the American party, had cameras to be used in searching for a possible intra-mercurial planet, but no mention is made of the fate of these observations.

The duration of totality at the American station was determined at 5m. 47s. instead of 5m. 42s. as predicted.

In consequence of the unfavourable meteorological conditions, the special investigations depending on the unusually long duration of totality were either unsuccessful or abandoned altogether.

Mr. Dyson, although he had to expose through thin clouds, obtained fairly good large-scale photographs of the corona; the small-scale plates show a considerable number of stars.

Mr. Newall is reported to have obtained good results with a grating spectrograph. Visual observation showed that the brightness of the green coronal ring was very uneven. A series of eight photographs with the polariscopic camera exhibit marked polarisation of the bright portions of the corona, especially in the case of the southern edge of the brightest streamer.

He was also successful in obtaining good photographs of the corona, which shows considerable similarity to that of last year.

The observations made to determine the *rotation* of the corona were unsuccessful.

M. de la Baume Pluvinel, who also observed among the mountains in Sumatra, announces partially successful results.

COMET a (1901).—A circular (No. 44) from the Centralstelle gives the following ephemeris for the new comet:—

Ephemeris for 12h. Berlin Mean Time.

1901.	R.A. h. m. s.		Decl. ° ′
May 24	6 19 16	...	+6 22·9

HISGEN'S VARIABLE, 13 (1900) CYGNI.—At the request of Father Hisgen, Prof. E. C. Pickering has had an examination made of the Harvard plates showing the star, and gives the resulting measures in *Astronomische Nachrichten* (Bd. 155, No. 3712). 181 plates were found covering the region, extending over the period 1887 November 30—1900 September 26.

After plotting the measured magnitudes to a time scale it was found that the star varies with moderate regularity in a period of 218 days. It has a magnitude of about 10·2 at maximum, and 13 or fainter at minimum.

THE PLANET SATURN.

SATURN now passes the meridian in the morning twilight, and is situated about 4° east of the planet Jupiter. The two objects will form an exceedingly interesting couplet in the southern sky during ensuing months, their times of southing and apparent distances being as follows:—

		Jupiter south. h. m		Saturn south. h. m.		Distance. °
June 15	...	13 9	...	13 28	...	5
July 15	...	10 55	...	11 21	...	6
Aug. 15	...	8 41	...	9 11	...	7
Sep. 15	...	6 40	...	7 6	...	6
Oct. 15	...	4 54	...	5 12	...	4
Nov. 15	...	3 14	...	3 19	...	1
Dec. 15	...	1 43	...	1 34	...	2

They will be evening stars during the late summer and in the autumn, but early in December will have approached too near to the sun for further observation. For telescopic scrutiny, the proximity of the two bodies will be found very convenient, but their low altitude of about 15° or 16° when due south will operate very unfavourably upon the character of the images.

It is a matter of common experience that Saturn will satisfactorily bear greater magnifying power than either Mars or Jupiter; but during the ensuing apparition moderate eyepieces will be best. Even with these, definition will be rarely good in latitudes so far north as Greenwich. The rings are now widely open, and their north side will continue to be presented to the earth until 1907. When Saturn is placed above the equator and traversing the zodiac from Pisces to Virgo, we see the southern surface of the rings, and the northern surface when he is below the equator and moving from Virgo to Pisces. The rings are turned edgeways towards us, and are practically invisible when the planet is in Virgo and Pisces.

Well-defined irregular markings are rare on Saturn. Dawes in January 1858 saw a bright spot and Asaph Hall followed a similar marking in December 1877, but it soon grew faint and disappeared. Several transits of the latter object were obtained, and a rotation period of 10h. 14m. 23·8s., agreeing nearly with Sir William Herschel's 10h. 16m. 0·4s. from a quintuple belt seen in 1793, was derived which may be regarded as very near the truth. But apart from these and a few other observations it must be confessed that little is certainly known with reference to irregular markings on Saturn. Hall, with the 26-inch Washington refractor, Barnard, with the 36-inch Lick refractor and other telescopes, Young, with the 23-inch at Princeton, Hough, with the 18½-inch at Chicago, and others have all systematically endeavoured to distinguish spots on the planet's globe and all have failed, except in the particular case alluded to. The cream of observational talent, assisted by the finest and best telescopes ever constructed, has proved that irregular markings sufficiently well pronounced to be distinctly visible are somewhat of a rarity. Yet it should be stated that certain other observers discern alleged spots with ease and in prolific numbers as well as under many varieties of shape and tint. Indeed, the Saturnian spots would appear to be as frequent and to have as many vagaries as the markings on Jupiter if we may accept the testimony of a few observers. Whether these things are objective realities or the products of visionaries remains to be proved by the severe tests which future researches will apply.

Saturn comes to conjunction with Jupiter at intervals of about twenty years, previous conjunctions having occurred on April 22, 1881, October 25, 1861, January 26, 1842, June 19, 1821, July 16, 1802, &c. The ensuing conjunction takes place on the morning of November 28 next at 6 h., when Jupiter will be 0° 27′ south of Saturn. In 1881 the planets were 1° 18′ apart, in 1861 0° 52′. Mr. Crommelin gives the results of some computations in the *Monthly Notices*, lxi. p. 118, which show that the distance of the centres of the two planets will be less than 1° between November 21 and December 5. The near approach of these attractive objects will form an event of considerable interest to the general public as well as to the astronomical world.

W. F. DENNING.

MARINE BIOLOGY IN LIVERPOOL.

THE Editor of NATURE invites me to write a short account of the marine biological investigations and the scientific fisheries work carried on of late years in the Liverpool district, and I have pleasure in complying with this request since it will enable me both (1) to acknowledge the services of friends and fellow-workers, and (2) to distinguish between three very different local bodies whose work is frequently—and perhaps not unnaturally—confounded even by marine biologists and even in Liverpool. These three bodies are the Liverpool Biological Society, the Liverpool Marine Biology Committee, and the Lancashire Sea-Fisheries Committee. They are perfectly distinct in organisation, control and object, and although the work they do is to some extent similar, still, as a result of friendly arrangement and cooperation, there has been absolutely no rivalry and no overlap or duplication of work such as might under other circumstances cause waste of time, funds and opportunity. Let me state briefly the position and work of each of these three bodies, all of which are now contributing actively to the elucidation of the marine biology of the Irish Sea.

I. *Liverpool Biological Society*.—This is a public scientific society in the town, like its well-known sister society, the Liverpool Geological Society. It meets monthly in the zoological department of University College, and all local lovers of nature are eligible for membership. The president this session is Prof. A. M. Paterson, and the hon. secretary Mr. J. A. Clubb, of the Free Public Museum. The past presidents include the professors of all the biological departments in University College (anatomy, physiology, botany and zoology), the head officials of the Public Museum and such well-known local biologists as the late Dr. Drysdale, Dr. Wiglesworth and Mr. Isaac Thompson. The Society is now publishing its fifteenth annual volume of *Proceedings and Transactions*. The *Proceedings* at the beginning of the volume contain a brief record of the proceedings at the meetings, including exhibits; while the *Transactions* consist of those papers which the council decides to print in full. Although the greater number of the papers in the published volumes deal with the marine animals and plants of the district, still biology in the widest sense is represented at the meetings and in the publications, and communications will be found on ornithology, entomology, palæontology, embryology, botany, anatomy, physiology and even archæology. It has been customary for the president in each session to invite some outside original worker in his own department of biology to come and address the Society. In this way important lectures have been given by Drs. Gaskell, Sorby and D. H. Scott, and by Profs. Howes, Haddon, Miall and others. The address this year will be given by Prof. D. J. Cunningham, on the lessons to be drawn from the condition of the skull and the brain in the microcephalic idiot.

II. *Liverpool Marine Biology Committee*.—This, in contradistinction to the Biological Society, is a private body. It is not a Committee of the Society or of anything else, but is an independent organisation. It was constituted at a meeting of biologists held at University College in March, 1885, for the purpose of carrying out a scheme of investigation of the local marine fauna and flora with the intention of publishing reports thereon. The dredging, trawling and other collecting expeditions organised by the Committee have been carried on intermittently since that time, and a considerable amount of material, both published and unpublished, has been accumulated. Fourteen annual reports of the Committee and five volumes dealing with the fauna and flora have been issued since 1886.

At an early stage of these investigations it became evident that a biological station or laboratory on the sea-shore, somewhere nearer the usual collecting grounds than Liverpool, would be a material assistance in the work. Consequently, the Committee in 1887 acquired a lease of Puffin Island, on the north coast of Anglesey, and established there the L.M.B.C. Puffin Island Station,[1] which formed the centre of their work at sea for five years. Later on, in 1892, finding that their work was extending, and that the very limited accommodation at Puffin Island was insufficient, they moved to the more commodious and more convenient biological station at Port Erin,[2] in the centre of the rich collecting grounds of the south end of the Isle of Man. This locality has proved so interesting and so perfectly suitable in every way that it is likely to remain as the permanent marine laboratory of the Liverpool naturalists; while the office of the Committee, the place of meetings, the publishing centre and the museum, is the zoological department of University College, Liverpool.

The Committee consists of twelve members who were chosen originally as being representative naturalists of Liverpool, Manchester, Southport, Chester and the Isle of Man—and most of these members are still active workers. Amongst our losses, by death, are Prof. Milnes Marshall, the Rev. H. H. Higgins and Mr. Francis Archer. The Committee subscribe amongst themselves and ask for contributions from their friends in Liverpool. In this way, aided by occasional grants from the British Association and other bodies, they have paid the expenses of numerous dredging expeditions, have maintained their small biological station, with a resident curator (now Mr. Herbert C. Chadwick), for fifteen years and have issued a considerable number of publications. The regular income for the last few years has averaged about 200*l*. per annum, but in addition several friends in Liverpool, amongst whom may be mentioned Mrs. George Holt and Mr. F. H. Gossage, have kindly placed sums in the hands of the present writer to be expended either in special expeditions or in the publication of memoirs requiring plates. Thus it will be seen that the funds at the disposal of the Committee, although, thanks to the generosity of friends and the economical management of our hon. treasurer, Mr. Thompson, they have sufficed up to the present, are evidently too small and too precarious to admit of much advance; and consequently an appeal will sooner or later have to be made for a permanent endowment of the Port Erin Biological Station.

The publications of the L.M.B.C. consist of:—(1) the annual report, issued primarily to subscribers and other friends in Liverpool. Although this report gives a brief account of the investigations undertaken during the year, still it is to be regarded, not mainly as a scientific, but rather as a business publication for the purpose of keeping the organisation together and in touch with the people of Liverpool. (2) The volumes of the "Fauna of Liverpool Bay," containing reprints of those papers communicated by members of the Committee, and others working at the laboratory, to the Liverpool Biological Society, and which deal with the local fauna and flora. These volumes are bound and issued at irregular intervals when sufficient material has accumulated.

[1] See NATURE, vol. xxxvi. p. 275. [2] See NATURE, vol. xlvi. p. 155.

Five volumes have now appeared, bearing the dates 1886, 89, 92, 95 and 1901. (3) The "L.M.B.C. Memoirs," a series of detailed descriptions of the structure of certain common typical animals and plants, chosen as representatives of their groups and dealt with by specialists. Memoirs on the following types have already appeared or are in the press: I. *Ascidia*, II. *Cardium*, III. *Echinus*, IV. *Codium*, V. *Alcyonium*, VI. *Lepeophtheirus* and *Lernaea*, and VII. *Lineus*. Several others are nearly ready, and about thirty-five in all have been arranged for. Amongst other L M.B.C workers whose names have not been mentioned are Mr. A. O. Walker, Mr. Arnold Watson, Mr. A. Leicester and Prof. Harvey Gibson.

III. *Lancashire Sea-Fisheries Committee*.—The district controlled by this Committee (recently amalgamated with the former Western Sea-Fisheries District to form what is now officially styled "The Lancashire and Western Sea-Fisheries District") is probably the largest, and in several respects the most important, of the sea-fisheries districts which have been established since 1890, in connection with the County Councils, round the coasts of England and Wales, under the Sea-Fisheries Regulation Act of 1888. The district extends from the Duddon, in Cumberland, to Cardigan, in South Wales, and thus runs for about 441 statute miles along the shores of the Irish Sea. It bounds in all nine counties and contains about 1500 square miles of sea. Nearly every kind of English sea-fishing is carried on within this district, including fish-trawling, line-fishing in all its branches, drift net, trammel net and draw net fishing; set nets and stake nets, weirs and hedge-baulks are also used. Besides these there is a very large shrimping industry which is carried on by the use of shrimp trawls, shank nets, hose nets and push nets. Lobsters, crabs and prawns are taken in many places, and there is a very large area of shell-fish beds—mussels, cockles and oysters.

The work of the Committee is mainly administrative, and is carried out by a superintendent, Mr. R. A. Dawson, who has at his command an efficient steamer and a staff of bailiffs. There is also a scientific department, of which the present writer is hon. director, and the work of which centres in Liverpool. In that department we have a central fisheries laboratory in University College, and a branch laboratory with sea-fish hatchery at Piel, near Barrow in the north of Lancashire. The fisheries assistant at Liverpool is Mr. James Johnstone, and the resident assistant in charge of the Piel Hatchery is Mr. Andrew Scott. Both these gentlemen are known to marine biologists by their investigations, those of Mr. Johnstone being on the mussel and the cockle, and those of Mr. Scott for the most part on Copepoda and fish-hatching.

The work of the scientific department of the Lancashire Sea-Fisheries is most varied throughout the year, and ranges from teaching fishermen and keeping up a fisheries museum to hatching fish, reporting on oysters, and carrying on research in regard to all kinds of fisheries problems. The following headings of sections in the last published annual report (the ninth) will give an idea of the scope of the work: required survey of fishing grounds, fish-hatching, spawning of mussel, statistics of shrimping grounds and fish, relation of deposits to shrimps, sporozoon parasite of the plaice, Copepod fish parasites, circulating fisheries exhibition, laboratory classes for fishermen, inspection of shell-fish beds, and the question of sewage contamination. In this report it is urged that "what we stand most in need of at present is full and accurate statistics in regard to our fisheries, and much more detailed information than we have as to the distribution round the coast both of fishes in all stages of growth and also of the lower animals with which they are associated and upon which they feed". . . "We must, in fact, get series of accurate observations which will give us fair samples of the more sedentary populations of our seas on the different grounds, such as trawling grounds, shrimping grounds, nurseries and spawning banks at the different seasons". . . "My contention, then, is that such an investigation of our seas must be made, that it is urgent and should be made now, and that the Irish Sea is favourably situated and circumstanced at present to be made a test case before undertaking the much wider and still more difficult expanse of the North Sea, complicated by international questions. The Irish Sea is of moderate and manageable dimensions. It is all bounded by British territory and by sea-fisheries authorities which might agree as to their regulations. It is a 'self-contained' fish area, containing both shallow and deep water, spawning banks, feeding grounds and nurseries. It has several laboratories (Liverpool, Dublin, Port Erin and Piel) on its borders which would form centres for investigation, and it is controlled by powerful sea-fisheries authorities, two of which at least (Lancashire and Ireland) are provided with excellent steamers which might combine in the work. All that is required, beyond a carefully considered scheme, is authority from Government to the local committees to carry out such work, and a subsidy for, say, five years, to meet the increased expense." It is pointed out that there are two methods by which the required survey of our seas might be effected:—(1) By forming a properly equipped Government department (in some respects like the Geological Survey), with laboratories and steamers and a scientific staff competent to tackle the scientific problems involved; and (2) by making use of existing organisations, giving fuller powers to the local committees, and by encouraging and enabling them to spend money on the necessary investigations in their own districts.

It has been found in Liverpool that the only effective way of teaching fishermen is by means of practical classes. Lectures of all kinds, followed by discussions long and short, demonstrations microscopic and otherwise, have been tried in vain, or with only qualified success. Of course the brighter spirits amongst them, the picked men, can be instructed by any method, but for the average fisherman it takes the patient hammering of hour after hour and day after day in a laboratory class, where you appeal, not only to his ears, but also to his eyes and his fingers, and where he makes and remakes his own preparations, cleans his own cover-glasses and focusses the microscope for himself, before he can understand and will believe what he is told and sees, and finally becomes convinced, for example, that he is really looking at a young fish inside a minute transparent egg caught on the surface of the sea, or that what he and his fellows have always stoutly maintained to be the spawn of flat fishes is after all only the egg-capsule of an Annelid.

After deciding that this was the best plan to adopt in applying technical instruction to the fisheries, we started these laboratory courses in Liverpool last spring (February 1900). Two courses were held last year, two are being held this spring, and two others will follow later in the summer. The Technical Instruction Committee defrayed the expenses of the fishermen. That is, they gave 5*l*. to each man to meet his travelling expenses and his board and lodging in Liverpool during the fortnight he was under instruction. No charge was made for instruction or for the use of the microscopes, dissecting instruments, material and reagents—everything necessary was supplied by the laboratory. The teaching was carried on by Mr. Johnstone under my supervision, and the whole course was entirely practical in character, each man examining everything for himself and working every day, both forenoon and afternoon. For details as to the work of the course I must refer to our report, but I may say, in conclusion, that the results were most encouraging, and that from the reports of the superintendent of fisheries to his committee there can be no doubt as to the success of the method in the eyes of the fishermen and of the sea-fisheries officers.

I must now have nearly reached the limits which the Editor asked me not to exceed, and so I fear I must not enter upon further details, although I should have liked to have told how Mr. Thompson and Mr. Scott are working at the Copepoda, Mr. Chadwick and Mr. Ascroft at plankton, Mr. Johnstone and Dr. Jenkins at fishery statistics, Mr. Cole at the nerves of the flat fishes, and others of my excellent assistants and colleagues at various other special problems. But I must be content for the present with the above sketch of the local marine biological and fisheries work which centres in Liverpool, and with the following expression of my strong convictions on two points. I feel certain—

(1) That for such work the great thing is friendly co-operation. The field is so enormous and the work so varied in its nature that there is room and use for many individuals of very different capabilities. And if the work is to be carried on without Government subsidy or large endowments it is necessary to attract and combine various local organisations, such as University, County Council, local scientific societies, and that characteristically English product the serious amateur who does excellent original scientific work.

(2) That this work is only beginning, and that a great future lies before marine biology in all its branches, including the application of scientific methods to the investigation of fisheries problems.

W. A. HERDMAN.

PUBLIC HEALTH IN AMERICA.

THE thirty-first annual report of the State Board of Health of Massachusetts, dealing with the work of the various departments during the year 1899, has lately been issued. These reports are mainly known to this country in connection with the original investigations on the treatment of water and sewage which have for many years past formed an important feature of the work undertaken by this Board of Health.

The practical outcome of these researches is seen in the recommendations made by the Board to cities and towns, no less than 79 applications for advice regarding the establishment of systems of water supply, drainage and sewerage having been dealt with during the year, and the Board have the satisfaction of reporting that at the end of this period every city in the State and 132 out of a total of 321 towns were provided with public water supplies. If the death-rate from typhoid fever over a series of years be taken as an index of the sanitary condition of a community, then, indeed, the State of Massachusetts has just cause for congratulation on the results of the enlightened policy in regard to questions of hygiene which has been so persistently pursued by, and has so prominently distinguished, its officials.

In the years 1871–75 the death-rate from typhoid fever in the cities, as well as in the State at large, was as high as 8·2 per 10,000. This figure has gradually been reduced to 2·6, and in the four years from 1896 to 1899 the rate has been further brought down to 2·4 per 10,000. Again, while in the period 1871–75 there was not a single city amongst the 31 in the State having a lower death-rate from typhoid fever than 2·7 per 10,000, in 1899 there were 24 such cities. The most noteworthy improvement was that of Lawrence, where the typhoid death-rate fell from a mean of 11·2 per 10,000 in 1886–90, and 7·7 in 1891–95, to 2·5 in the four years 1896–99, following the introduction of sand filtration of the water from the Merrimack river supplied to this city.

In regard to consumption, the Board is able to make a no less satisfactory report, the decline in mortality from this disease having continued with a fairly steady and uniform rate throughout the past fifty years, reaching in 1899 18·7 per 10,000. In commenting upon this fact it is pointed out that it is between the ages of 15 and 60 that consumption is most fatal, and that in 1894 and 1895, out of 1000 deaths from all causes in Massachusetts between these ages 288 were due to tuberculosis, whilst in Paris the figures for the same period of life were 400 and in Vienna 459, or nearly one-half of all the deaths at that age. Emphasis is laid upon the necessity for taking further precautions for the control and prevention of this most destructive disease, a sentiment which will be given practical effect to this year in England at the British Congress for the Prevention of Consumption, presided over by the King, to be held in London in July.

Massachusetts is, however, not the only State in America which is alive to the urgency of dealing effectively with this disease. Michigan, which supports a State Agricultural College, has recently issued a valuable *Bulletin* in which practical methods are suggested for combating this scourge, based upon careful scientific experiments. The writer of the *Bulletin* states that tuberculosis causes more than twice as many deaths in Michigan as any other single contagious disease, and Dr. Keen, of Rhode Island, has calculated that more than 100,000 persons annually die of consumption in America, and that at this rate out of the 70,000,000 people in the United States 10,000,000 are practically condemned to death through tuberculosis.

In discussing the unusual prevalence of small pox which has characterised the period covered by the report, a special table has been appended showing the comparative fatality of the vaccinated and unvaccinated respectively. This table is based upon carefully compiled statistics kept between the years 1885 and 1899, and shows that the deaths from small pox among the vaccinated was 7·6 per cent. and among the unvaccinated 26·0 per cent., or more than three times as great in the latter case during these fourteen years.

In the pathological department of the Board much attention has been bestowed upon the preparation of diphtheria antitoxin, and a large number of examinations were made for the verification of diphtheria germs. The work of this department has largely increased during the year, for considerable quantities of the antitoxin have been used for the immunisation of healthy persons who have been exposed to the infection of diphtheria, whilst at the Children's Hospital, an institution at which several hundred patients are annually received for treatment, medical and surgical, but not for infectious diseases, it has been the custom to immunise each patient with diphtheria antitoxin soon after admittance.

No reference is made to the preparation of antityphoid serum, neither, apparently, have any investigations been carried out with regard to it. Likewise we note that tetanus antitoxin is no longer prepared, the reason given for its discontinuance being that the demand for the serum was small and irregular, and its application usually delayed until the patient was past recovery.

An interesting section of the report deals with the results of the food and drug inspections. Although the use of preservatives or any foreign substance in milk is illegal, 11·6 per cent. of the samples examined contained a preservative, in the largest number of cases formaldehyde being employed, which is widely used in the United States under the name of "Freezine." A pamphlet setting forth the special advantages of this preservative states that "it is not an adulterant, that it immediately evaporates, so that it defies detection as soon as it has rendered all the bacteria inert, it is beneficial to the health of infants, many of whom have been saved from sickness and even death by a liberal use of 'Freezine' in the milk!"

Butter, we are informed, was specially tested for the presence of boracic acid in consequence of the alleged extensive use of this ingredient in Great Britain. None was found, which may be attributed to the custom which prevails to a much larger extent in America than in England of eating salt butter, in which case the use of an additional preservative would be superfluous.

The above brief sketch may give some idea of the general scope of the work undertaken by public boards of health in America. It serves to emphasise, perhaps, that Great Britain is still waiting for an Imperial Board of Health, and that what individual States in America can accomplish we as an Empire are powerless to achieve.

G. C. FRANKLAND.

THE EXTENSION OF KNOWLEDGE.

AN inspiring address, dealing with the influence of universities upon national life, delivered at the Johns Hopkins University at the last commemoration day by Dr. D. J. Hill, assistant secretary of State, is published in one of the University Circulars just received. Students of human history well know that the pursuit of knowledge has been the fundamental factor of progress through many centuries. The earliest universities in Europe were associations of teachers and students with this aim, and they exerted a powerful influence upon society long before their existence was recognised by Church or State. "It is not too much to say," remarks Dr. Hill, "that the transformation of Europe which marks the distinction between mediæval and modern times has been chiefly the work of the universities, for they have exercised the most potent influence upon social progress and popular liberty of any single class of human institutions." The spirit which has led to the establishment of so many institutions for higher education in the United States, by private munificence, seems to have been inherited from the Pilgrim Fathers. Even when the colony of Massachusetts numbered only four thousand, it was decided to found a college; but the resolution is less astonishing when it is remembered that among the first six hundred settlers one in every thirty was a graduate of Cambridge.

Dr. Hill concluded his address by referring to the changing conditions of life, and the need for all who are concerned with education to recognise their new obligations and make themselves equal to their modern mission. This part of the address is reprinted below.

"It is no longer a question of merely popular education, although that is always fundamental; it is a question of the higher and the highest education that confronts us now. We have passed the primary stage, the common schools are established, the colleges exist in sufficient numbers, and even universities do not need to be multiplied. We have sought the safeguard of liberty in the universal diffusion of knowledge, but it is not the mere rudiments that have saved us in any great emergency. In what crisis of diplomacy, in what complicated question of finance, in what quandary of economic policy, in what problem of constitutional interpretation have the elementary arts furnished saving knowledge to the nation? No, in every grave complication, it is not these mere elements that are needed—though they indeed are always indispensable—but some broader and superior knowledge, some finer detail of information, some more acute discrimination, some keener analysis of evidence, some more penetrating intellectual vision or more ripened judgment—the fruits of long and serious study, which a whole nation of half-trained persons could not supply; and in the moment of perplexity it is to some quiet scholar or studious thinker that the nation makes appeal; and when he speaks light dawns, the clouds are swept away, and the path of action is made plain. . . .

"The time has gone by when merely individual and local efforts can secure to our country its place among the nations; for we have entered upon a period of world-relations—of world competition, of world policies and of world beneficence—from which it is impossible to recede. Our only hope of great national prosperity lies in the possession of a world-culture that will place us on a level with the best thought and highest knowledge attainable by man. Every humblest toiler on the farm and in the factory will henceforth be affected by the discoveries of science, the movements of foreign commerce and the resources of national industry. We have won our present industrial pre-eminence, without the advantages of technical education, through the fertility of our soil and a native genius for construction and organisation; but the time must come, and it may not be far distant, when the highest technical education will be necessary to the success of the simplest American industry. The competition of the hand is rapidly resolving itself into the competition of the brain, and the comprehension, guidance and application of natural forces in accordance with natural laws become questions of national consequence.

"Give us, then, O learned doctors, more discoveries of science, for we know not what new revelations may yet burst forth from your laboratories; give us more of art, for it is only through the channels of expression by word and sign and symbol that new truth can be lodged in the minds of the people; give us more of history, for it is only by conning the lessons of experience that the children of men grow wiser; give us more of literature, for it is only through the life of letters that man rises to the full comprehension of himself; give us more of ethics and philosophy, for it is only in the light of great principles that character becomes firm and conduct noble; let earth, and sea, and sky, and the stars in their courses, the long struggle of man and the story of his aspirations, the tongues of the busy day and the silence of the voiceless night, the instincts that stir us to passion and the still small voice that drops its calm out of eternity, all teach us the ways of creation and the mystery of our divine descent; for it is through the totality of their culture that nations rise, and through ignorance or defiance of unbending laws that nations fall."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Dr. G. C. Bourne has been appointed to represent the University on the Board of Governors of Coopers Hill College.

The seventh Robert Boyle lecture will be delivered by Prof. Sylvanus Thompson on June 6; the subject will be "Magnetism in Growth."

Mr. H. B. Hartley, scholar of Balliol College, has been elected to a fellowship at that college as science tutor in succession to the late Sir John Conroy. Mr. Hartley obtained a first class in chemistry and mineralogy in 1900.

CAMBRIDGE.—Sir W. Martin Conway has been elected Slade professor of fine art in succession to Dr. Waldstein.

Seventy-three men and twenty-six women have acquitted themselves so as to deserve mathematical honours in the first part of the tripos.

It is proposed to appropriate from the Benefaction Fund a sum of 21,000*l.* to the new botany school building, and 16,000*l.*, together with some 5500*l.* specially contributed, to the new medical school building.

Prof. Macalister is appointed an examiner in anatomy for medical degrees in the place of Dr. Barclay-Smith.

THE field studies in natural history arranged by Mr. David Houston for the Essex Technical Instruction Committee provide an excellent means of becoming familiar with nature, and should be of special assistance to teachers who desire to adopt the scheme of nature study recently issued for rural schools by the Board of Education. Rambles are arranged for Saturday afternoons, and demonstrations in general natural history are given by the director, so that an introductory knowledge of the natural vegetation of the county can be obtained in a pleasant way. A ten days' vacation course has been arranged to be held in the New Forest, from August 12 to 22. The programme of the course, and the field notes appended to it, show that the members of the party will have the opportunity of spending a profitable short holiday in the New Forest and neighbourhood.

APPROVAL of the Government Education Bill has been expressed by several educational bodies concerned with technical and secondary education. The chief difficulties raised by the Bill relate to the constitution of the local authorities to be responsible for the educational work of their respective districts, and the funds which are to be available for technical and secondary education. At present technical instruction committees administer the "whisky money," and in a few places an additional penny rate is also levied. The new Bill proposes to let the local authority administer these funds, and to give it the power to levy another penny rate; but as the funds are to be used for both secondary and technical education, the extension of rating power is wholly inadequate to the requirements. This view is held by the council of the Association of Technical Institutions, and in order to give expression to it a special meeting of the Association will shortly be held. Resolutions will be brought forward to the effect that, while the general principles of the Bill are approved, adequate provision must be made to defray the necessary additional charges in respect of secondary education which will fall upon the local authorities, and technical instruction must be provided for before the residue available under the Local Taxation (Customs and Excise) Act is used for purposes of secondary education in general.

SCIENTIFIC SERIALS.

Annalen der Physik, May.—Researches on the normal cell, especially the Weston element, by W. Jaeger and St. Lindeck. This paper contains the results of an exhaustive experimental study of the Clark and Weston cells. The researches of E. Cohen had thrown some doubts upon the suitability of the Weston cell as a standard, especially in the neighbourhood of 0° C. In the present paper it is shown that these irregularities only occur about 0° C. and with the cell containing 14·3 per cent. amalgam, no trace of any irregular deviations appearing when the cell is used at 10° C. or higher temperatures. Further, if the amalgam is made slightly weaker in cadmium, 12 per cent. or 13 per cent., these irregularities near 0° disappear, and the measurements are trustworthy at all temperatures. It is concluded that the strictures of Cohen with regard to this cell are not justified, and that the Weston element is eminently suitable as a standard of electromotive force.—The calculation of isotherms, by C. Dieterici. The fundamental equation of condition of van der Waals is modified, in part empirically, without assuming that the cohesion pressure and the volume correction are determined, and the results applied to the measurements of Young on isopentane and benzene, of Ramsay and Young on ether and water, and of Cailletet and Matthias on sulphur dioxide and carbonic acid.—Contribution to the theory of electric discharges in gases, by J. Stark.—On the variation of the dielectric constant with pressure and temperature, by J. Koenigsberger.—The constancy of the sparking potential, by K. R. Johnson.—On Jaumann's clear J-surface, by A. Korn. A discussion of a phenomenon first observed by Jaumann in a vacuum tube.—The internal friction of argon and its variation with temperature, by H. Schultze. The absolute value found for the viscosity coefficient of argon is practically identical with that previously determined by Lord Rayleigh, but the alteration of viscosity with temperature is found to be somewhat greater according to the author's experiments. The formula suggested by Sutherland gives a good approximation to the results of the experiments.—On the internal friction of gases and its change with the temperature, by P. Breitenbach. An application of Sutherland's formula to the experiments previously published by the author on the temperature coefficient of the viscosity of air, ethylene, carbonic acid, hydrogen and methyl chloride. The agreement between the calculated and experimental results is so good as to amount to a proof of Sutherland's theory.—The equilibrium figures of powders, by F. Auerbach.—On the influence of temperature on the elasticity of metals, by C. Schaefer. Experiments were carried out on nine metals, and the value of the torsion modulus measured at – 186° C., – 70° C. and about 20° C. If the temperature coefficients of the different metals are plotted as ordinates, and the melting points as abscissæ, a smooth curve passes through the whole of the results.—Remarks on a paper of T. Middel on the cause of the thermal change of delicacy in balances, by W. Felgentraeger.—Liquid crystals, by O. Lehmann. A reply to some remarks of G. Tammann.—On the distribution of electricity on an ellipsoid, by G. Jaeger.

Symons's Meteorological Magazine for May contains a useful reference table of the annual means and extremes of the meteorological observations taken at Camden Square for each of the forty years 1858–97. During the years 1898 and 1899 Mr. Symons gave for each month the means and extremes for the various elements, and the present third set of tables completes this unique and valuable record of the climate of London. It may not be out of place to quote a few of the extreme values of the period in question, which are shown by a glance at the table, although we have referred to most of them on former occasions. The highest solar radiation temperature (since 1870) was 137°·7 in 1881, and the lowest terrestrial radiation temperatures (since 1860) were 0°·6 in the same year and 0°·5 in 1867. The extremes in the screen were 94°·6 in 1881 and 6°·7 in 1867. The same low reading occurred in 1860, and 7°·3 in the severe frost of 1895. The greatest rainfall (34·08 inches) occurred in 1878, and the least (16·93 inches) in 1864.

SOCIETIES AND ACADEMIES.

LONDON

Anthropological Institute, May 14.—Mr. R. Shelford, of Sarawak, exhibited a number of carved bamboos and commented on the elements of Dyak decorative art.—Mr. W. MacDougall read a paper by Dr. Hose and himself on the animal cults of Sarawak. He showed that though many of them exhibit elements frequently associated with totemism, such as the respect paid to an animal believed to be the resting-place of the soul of a deceased ancestor, totemism itself could not be regarded as the starting-point of any of the cults, and was at most only present in a rudimentary stage. He also gave details as to the beliefs of the Sea Dyaks about the Nyarong or spirit-helper believed to be acquired by some men in dreams.

EDINBURGH.

Royal Society, May 8.—Dr. Burgess in the chair.—Prof. Copeland and Dr. J. Halm, in further notes on the new star in Perseus, gave a description of the changes which had accompanied the star's decrease in brightness. One of the most interesting features was the periodicity which had recently established itself, indicating a period of three to five days with a possible longer period of several weeks. The corresponding changes in the spectrum were also discussed, the apparent shifting of certain bands being explained as due to the fading of the one and the relative brightening of the other of two overlapping bands. Broadly speaking, the change in the spectrum had been towards the nebular type. It was suggested that the absorption bands flanking the bright bands were an effect of high internal pressure.—Prof. John Gibson read a paper on certain relations between the electrical conductivity and the chemical character of solutions, following up a previous communication published three years ago. The paper was based upon a large number of experiments, some of which had been going on for years and were not yet completed. The broad principle underlying the results he had obtained was that in solutions inter-molecular reactions tend towards maximum specific electrical conductivity. In one series of experiments solutions of hydrochloric acid of varying concentration were formed and a small proportionate quantity of chromic anhydride added to each. In strong solutions above the concentration which gives the maximum specific conductivity, the reaction, represented by the equation $12HCl + 2CrO_3 = 2CrCl_3 + 6H_2O + 3Cl_2$ and indicated to the eye by the change in colour, went on more rapidly the further removed the concentration was from that which corresponds to the maximum specific conductivity. In one experiment the critical concentration of 18·2 per cent. was used and the mixture kept in the dark. The reaction is not yet complete, although three years have elapsed. With a 20 per cent. solution the reaction was completed in about six months, and with a 24 per cent. solution in less than one month. Similar results were obtained with other solutions involving more rapid reactions, requiring for their completion times comprised within a small number of weeks or even minutes. In the case of sugar solutions another determining factor came in, namely, the viscosity, a diminution in which by the destruction of the sugar by sulphuric acid increases the conductivity independently of change in concentration. An interesting illustration of the same principle was afforded by the fact that in vinous fermentation a greater concentration than about 14 per cent. cannot be obtained. By making a series of artificial musts with proper proportions of salts, sugar and alcohol so as to represent approximately successive stages of the fermentation, Dr. Gibson found that the conductivity approached a maximum as the concentration of alcohol approached 14 per cent. The paper ended with a novel and interesting discussion of the phenomena of plant life along the same broad physico-chemical lines. The *rôle* of the inorganic salts necessarily present in the sap, the special usefulness of certain salts and the influence of varying concentration were discussed and connected with principles in regard to photochemical action and chemical action generally embodied in two short papers read in 1897 and published in the Society's *Proceedings*.—Prof. George Forbes, F.R.S., read an additional note on the Ultra-Neptunian planet the existence of which is indicated by its action on comets, supplementing papers on the same subject published twenty years ago. The general idea was that comets were attracted into the solar system by the action of outlying planets; and there were seven comets having aphelion positions corresponding with positions of a planet revolving round the sun at a distance 100 times that of the earth, with a period of about 1000 years. It was suggested that this planet, by its disturbing action on the comet of 1264 and 1556, which had not reappeared as expected in 1848, had so altered the elements of the orbit as to make it no longer recognisable; and reasons were given in favour of the identification of the lost comet with either the comet 1844 (3) or the comet 1843 (2), both of which had parabolic orbits assigned. If these were assumed to be ellipses of the proper size the aphelion positions would not be far removed from the positions occupied by the supposed planet. To produce the changes demanded in the orbit the mass of the supposed planet would, however, require to be greater than that of Jupiter.

PARIS.

Academy of Sciences, May 20.—M. Fouqué in the chair.—On the total eclipse of May 18, by M. J. Janssen. A short report on observations of the recent eclipse by M. de la Baume, at Sumatra. The rotation of the sun's corona, and the presence of Fraunhofer's lines in the light thereof, have not been confirmed.—Researches on the condition of alumina in soils, by M. T. Schlœsing. A number of specimens of earth from Madagascar were found to contain considerable quantities of alumina, either in the free state or in the form of a silicate readily attacked by dilute caustic soda solution. The greater part of the alumina or the silicate exists in a pulverulent, sandy state, and is not the cause of the tenacity of the soil; it has no adverse influence on vegetation.—M. Laveran was elected to fill the vacancy in the Section of Medicine and Surgery caused by the decease of M. Potain.—On the eclipse of Jupiter's fourth satellite, observed at Paris, May 17, 1901, by M. G. Bigourdan.—Observations of the brightness of Nova Persei, by M. Luizet. The variations in the brightness of this star are said to show no regular periodicity.—On regular groups of a finite order, by M. Léon Autonne.—On the molecular depressions of the temperature of maximum density of water produced by the dissolution of the chlorides, bromides and iodides of potassium, sodium, rubidium, lithium and ammonium; the relations between these depressions, by M. L. C. de Coppet. The experimental results are given in tabular form. The lowering of the temperature of maximum density is proportional to the quantity of salt dissolved, whilst the *molecular* lowering is almost constant. Lithium salts, however, are an exception to the latter rule, their molecular lowering increasing with the concentration. The salts of sodium are the most, and those of lithium the least, active. Iodides produce a greater depression than bromides, and bromides than chlorides, the relations between the observed values being the same for all the metals of the group.—Alcohols and calcium carbide, by M. Pierre Lefebvre. A continuation of previous work on the subject. In the present paper are given the results of the analysis of the gases produced by the action of the vapours of amyl, isobutyl, ethyl or methyl alcohols on heated calcium carbide.—On the condensation of acetylenic hydrocarbons with formaldehyde; synthesis of primary acetylenic alcohols, by MM. C. Moureu and H. Desmots. The action of the sodium derivatives of œnanthylidene or phenylacetylene on the solid polymeride of formaldehyde results in the formation of two new alcohols. Amylpropiolic alcohol boils at 98° under 13 mm. pressure, and has a specific gravity 0·8983 at 0°, whilst phenylpropiolic alcohol boils at 139° under 16 mm. pressure, and has a specific gravity 1·0811 at 0°; both are colourless, oily liquids.—Action of acid chlorides on ethers in presence of zinc, by M. P. Freundler. Remarks on a recent paper by M. Descudé.—Oxidation of primary alcohols by contact action, by M. J. A. Trillat. All primary aliphatic alcohols are oxidised when a mixture of air with the vapour of the alcohol is passed over a heated platinum spiral, and it is possible to limit the reaction to the formation of the corresponding aldehydes; the presence of water vapour appears to favour the oxidation. The use of porous substances, such as platinum black, tends to the production of acids rather than aldehydes. Acetals are also produced, at any rate from the lower alcohols; their formation is a reversible reaction.—On the substitution of zinc-white for white-lead in oil painting, by M. A. Livache. According to the author's experiments, the injurious white-lead in oil paints may be successfully replaced by zinc-white, provided certain conditions are observed.—The evolutionary cycle of *Orthonectides*, by MM. Maurice Caullery and Félix Mesnil.—On a glucoside characteristic of the germinating period of the beech, by M. P. Tailleur. The beech, in its germinating stage, contains a glucoside and a corresponding ferment which, in the presence of water, give rise to methyl salicylate and glucose, the latter being assimilated by the plant. The reaction is localised in the hypocotyledonous axis, and does not occur in the seed or in the old plant.—On the petrographic classification of the schists of Casanna and the Alps of Valais, by M. L. Duparc. A description of seven types of schist.—On the electrolysis of animal tissues, by MM. Bordier and Gilet. The fall in strength observed on the reversal of a current passed through animal tissues, is not observed to any appreciable extent if the tissues at the level of the electrodes are impregnated with an electrolyte.—On the formation of urea by the oxidation of albumin by means of ammonium persulphate, by M. L. Hugounenq. Under favourable conditions, about 5 per cent. of urea may be obtained by the oxidation of egg albumen by ammonium persulphate in alkaline solution.—New seismological observations at Grenoble, by M. W. Kilian.

WATER-POWER.

An Outline of the Development and Application of the Energy of Flowing Water. By Joseph P. Frizell. Pp. vii + 563. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1901.)

WATER-POWER, as developed in waterfalls, has been brought prominently into notice in recent years as an important source of power, owing to the facilities afforded by electricity of transmitting it to a distance; so that a small portion of the Niagara Falls and numerous minor falls have been utilised for supplying power economically for electric lighting, traction, and other purposes, to places many miles distant from the falls. The author, however, of this volume desires to direct attention to the more widespread sources of water-power contained in streams and rivers, which can be utilised either by taking advantage of the natural fall by means of suitable works, or by storing up the flow in flood-time in reservoirs formed by constructing dams across the higher parts of river valleys; and the water thus collected can be converted directly into power by using the available fall below the dam, which, however, is reduced in proportion as the water-level of the reservoir is lowered, or it can be employed in supplementing the discharge of the river below the dam during its low stage, so that the flow when used for driving hydraulic motors may never fall below a definite volume. The author points out that whereas in recent times water-power has been to a great extent superseded by steam-power, owing to the cheapness of fuel and improvements in steam engines, timber has already become much less plentiful in the United States, and even coal will in time be exhausted; whilst the sources of water-power will always remain, and have already become more available by the adoption of electrical transmission, which in its turn has led to many notable developments and improvements in the utilisation of power. Undoubtedly vast sources of power produced by the sun's heat are continually running to waste in rivers and streams, as evidenced by the estimate quoted by the author, that the power derivable from the St. Lawrence and its tributaries is nearly equal to that obtainable from all the coal raised yearly in the United States. The difficulty consists in rendering this power economically available, for a high fall and a regular flow furnish the most efficient source of water-power; whereas the fall of rivers is, for the most part, moderate and spread over long distances, and their flow very variable, more especially in the upper part of their course, where the fall is the greatest. It is, therefore, quite natural that waterfalls have been resorted to as a source of water-power, and for transmission to a distance, especially where they occur at some distance from the source of a river, and consequently possess a more regular flow; whereas the utilisation of the more ordinary flow of rivers, except for local purposes, seems destined to have to wait till a considerable increase in the price of fuel and the absorption of the most advantageous sources of water-power render it necessary to turn to less economical supplies. Where a river has a rapid fall for a considerable distance, it may be quite practicable to develop largely its available water-power, by regulating its flow by the construction of a reservoir by means of a dam of moderate height across the upper part of its valley, so as to render its discharge always adequate to actuate turbines placed at suitable points along its course.

After an introductory chapter upon natural water-courses, including a computation of the *flowage*, or raising of the surface and modification of the slope of a stream by a dam put across it, the author treats of the various forms of dams constructed across rivers and streams, in ten chapters extending over 209 pages, embracing in his descriptions fixed weirs and some forms of movable weirs, as well as earthen and masonry reservoir dams, with their methods of construction and some notable failures. Such works, considered here as applicable to the development of water-power, constitute essential constructions for the improvement of rivers for navigation, and for forming storage reservoirs for the water-supply of towns, which have been often described in books and papers relating to these branches of hydraulic engineering; and the author only enters in the latter half of his book upon the consideration of hydraulic motors, and the modes of transmission of the power thus obtained, which more specially appertain to his subject. Three chapters are devoted to the methods of conveying the water to the motors, and the arrangements for the regulation of the supply and the power; whilst the various forms of water-wheels and of turbines are described in two consecutive chapters. Some instances are next given of the utilisation of natural water-powers in the United States; and it is pointed out that the plan formerly sometimes adopted of dividing a considerable fall into two or three parts, so as to command a large area of ground for the mills, is an expensive system in regard to the motors, and wasteful of the power, and that with modern methods of distribution it is expedient to make use of the entire head. The most important and special part of the book, however, is contained in the following five chapters, in which the various methods resorted to for the transmission of power are considered, and some interesting examples of notable power-houses are described. The forms of transmission dealt with are shafting and wire ropes, hydraulic transmission, transmission by compressed air, and electrical transmission. All these methods of transmission and distribution of power have their respective utility, but they differ considerably in the distance to which they can act with efficiency. Thus shafting is useful for transmitting power throughout a mill or manufactory; but beyond three or four hundred feet wire ropes are more economical, and can be employed with advantage up to about a mile. Hydraulic transmission is valuable in storing up power for intermittent working, as required at docks and large canal locks; but its efficiency for driving machines at a distance of about a mile is only 50 per cent. Air compressed by means of water-power has been transmitted considerable distances for boring the headings of long alpine tunnels, which it has also served to ventilate; and compressed air has been used for the transmission of power in a mine in the United States to a distance of three miles; but the changes of temperature produced in the compression and expansion of the air necessitate special arrangements to avoid considerable loss of efficiency. Electrical transmission, the most modern and most effective method of utilising power at a distance from the place where it is generated, has notably augmented the value of the water-power of falls; for it has enabled the power-house to be established at the source of the power, and the power developed to be distributed to manufactories situated in the most convenient localities, far removed from the generating station. Thus the Telluride Power Transmission Company, at Provo, in Utah, transmits 2000 h.p. by electricity a distance of 55 miles, at the high voltage of 40,000 volts; whilst the Southern California Power Company, possessing a head of water of 750 feet at Santa Ana Canyon near Redlands, develops 4000 h.p., and obtaining a current at 750 volts transforms it to 33,000 volts and transmits it 80 miles to Los Angeles. In the chapter on "The Power-House," the general arrangements of such establishments are explained, and the power-houses at Lachine Rapids, on the St. Lawrence, at Mechanicsville, on the Hudson 18 miles above Albany, and at Sault Sainte Marie, on the rapids between Lake Superior and Lake Huron, are described.

The book is illustrated by two hundred and thirty-two drawings, sections and diagrams, distributed throughout the text, and is furnished with an index; but it does not contain any tables of contents of the twenty-five chapters, beyond a short title at the head of each, or any list of the illustrations. The materials for the volume have been, to a large extent, collected from the most noteworthy records of engineering societies and pages of engineering journals, as well as from plans of works carried out; and the principles involved and the results aimed at have been presented in a condensed and readable form. The book should prove useful in directing attention to the enhanced value of water-power, especially in view of the very important assistance afforded it by electrical transmission.

AN ANGLO-AMERICAN WORK ON THE MARKET GARDEN.

The Principles of Vegetable Gardening. By L. H. Bailey. Pp. x+458. (London: Macmillan and Co. Ltd., 1901.) Price 4*s.* 6*d.* net.

THIS work is one of a "Rural Science Series," edited by an American author, but it is by no means the best. Its principal fault is that in covering too much ground it fails to treat with thoroughness the numerous subjects which are included in the seven chapters described in the table of contents. The most important of these subjects are "The Soil and its Treatment," "Glass" in relation to glass culture, "Seeds and Seedage," the last a word quite new to the industry in England, the meaning of which is not absolutely clear, and "The Management of the Vegetable Garden."

In market garden culture success depends upon approximate perfection in the soil, the seed and the management; for the realisation of profit a further qualification must be added—marketing. Nor does the arrangement of the chapter simplify matters; a number of quotations from other authors, printed in small type, are introduced in order to show the reader what soil to select, but while these authorities do not absolutely agree, the majority select a deep sandy loam. Such a soil may be found under garden cultivation in Bedfordshire and in the potato growing districts of the Vale of York, but before a clay loam with a clay subsoil is condemned the reader should see farm gardening on the London clay and in the Lea Valley.

A large proportion of this important chapter is devoted to "Fertilisers," but stable manure, which is the foundation of early as of heavy crops, and of double and triple crops, is barely mentioned; indeed, excepting in a brief reference to the preparation of hot beds under glass, stable manure is absolutely unmentioned in the copious index. We remember, on visiting the extensive gardens attached to the great experiment station of New York State at Geneva, being informed how much the management owed to an English gardener. The editor of this work would have largely added to its value had he interviewed such a man, or an English market gardener of eminence.

The subject of "Seeds" is more fully treated, but in the whole 50 pages the details for which the practitioner will look are in large part conspicuously absent. The chapter is largely composed of useful figures drawn from the reports of experiment stations, but it has no very direct bearing upon the gardening industry. Nor can we speak more highly of the treatment of the next essential subject, "Management," which might be better arranged and which is abundantly fortified with quotations; there is, indeed, much that is useful, but if a grower seeks advice of a practical character he will not always find it. At the end of the chapter there are some recommendations which are intended to help the gardener to preserve his crops from the attacks of insects and fungi; but when we say that the most destructive of all soil insects, the wire worm, *Elater sp.*, is dismissed in half a dozen lines, we do not misrepresent the extent of the information. The gardener is wisely recommended to make Paris green into a paste, but in this country it is not sold in any other form.

The second part of the book, in which crops are discussed in greater detail, is much better arranged, although the author has adopted a form of classification which, if ingenious, has its difficulties. He groups the plants of the vegetable garden as roots, tubers, bulbs, salads, pulse, solanaceous crops and so on, but this arrangement is quite unscientific; the turnips and the beet, for example, classed as roots, are bulbs, while the potato, if a tuber, is also a member of the solanaceæ. Again, cabbages and the cauliflower are classed as cole crops, but both belong to the same family as the radish and rutabaga or swede turnip, both of which are classed as roots. Here we notice a curious error: "The rutabaga (is) known in England as Swedish turnip and turnip rooted cabbage, and in French as Chou navet." The French equivalent for swede, which is unknown in England as turnip rooted cabbage, is rutabaga. Let us add that although many of the illustrations are exceptionally good, that intended to represent the turnip is ludicrous as applied to the improved plant.

This part of the work is, however, by far the best, treating as it does of many plants peculiar to the United States, as well as of those common to the gardening of this country, but even here we find scrappiness and irregularity of treatment. To the cultivation of celery, for example, considerable space is devoted, and this is well utilised, whereas the pea is dismissed with a brief discussion, and the potato, of which so much more should be said, receives notice of quite an inadequate character. The author tells us that potatoes are planted in drills 3 to 3½ ft. apart, and that if pieces of tubers are cut to one eye, 8 to 10 bushels will be required to plant an acre; also that the yield averages about 75 bushels—or less than two tons to the acre. These statements, like many others, do not apply to British or to the best American practice. The farmer cropping in the poorer soil of the open field plants 28 to 30 inches apart; he employs 22 to 25 bushels of seed, seldom cutting it, and then only once, whereas a two ton crop would mean financial ruin. For facts relating to the size and selection of seed, the best size of cut sets, the method of box sprouting for early crops and the most economical methods of manuring, we look in vain.

We notice with pleasure from the quotations made that in the United States details are collected in relation to the area of land devoted to various market garden crops. The figures, and they relate to 1891, are in some cases remarkable; thus, asparagus covered 37,970 acres, whereas potatoes were grown on only 28,000. Similarly, the area devoted to seed production is shown in relation to 40 varieties. Again, 25 pages are devoted to a list of works by other authorities, with descriptive notes, and bulletins issued by the various experiment stations upon subjects connected with vegetable gardening. All this is useful to the American reader. One of the most practical remarks in the book is that in which the author says that if a man is only a plant grower and not a good business man he will probably be a slave to the salesman, but where the grower occupies a large area and possesses sufficient capital to work it he can dictate to the market.

We are sorry not to be able to give this work unqualified praise; it is admirably printed and illustrated, and will afford help to those who possess a knowledge of principles. We would conclude, however, with the remark that the principles which we recognise in England are identical with those which are taught in the United States, and we venture to believe that our practice and that followed in the Northern States have more in common than the practices of the farmers and gardeners of the north and south. The author does not fully comply with these requirements. It is true that a student may refer to a work of the same series on "Soil," but we think the author would have acted wisely had he devoted a short chapter to a description of soil, its varied character and composition, how it is improved by culture, and why it is adapted to particular crops. Similarly, a definition of the principles which underlie the practice of manuring might have found a place—and above all, for gardeners know a great deal more about the management of dung than of artificial fertilisers, the importance of chemical manures and the *rôle* they play might have been more fully recognised. Although, therefore, the book is written primarily for the American reader, there is no reason why it should not have been made as interesting and instructive to the great constituency on this side of the Atlantic.

LIBYANS AND EGYPTIANS.

Libyan Notes. By D. Randall-Maciver, M.A., and A. Wilkin, B.A. Pp. 113; 25 plates. (London: Macmillan and Co., Ltd., 1901.) Price 20*s.* net.

THE volume before us is, as the writers say, the result of an expedition to Algeria undertaken in the year 1900 with the view of obtaining such information as would lead to the solution of the vexed question of the early connection of the Berber tribes with Egypt. This handsome publication contains fifteen chapters, which are illustrated by a large number of beautifully executed plates, and deals in an exhaustive manner with subjects which appeal as much to the anthropologist in general as to the Egyptologist in particular. The writers begin their observations by references to the pictures of the Libyans which are found painted in Egyptian tombs, and from which we learn that this people had fair skins and beards and blue eyes; such pictures belong to the period of the XVIIIth and XIXth dynasties, but it does not follow that they represent, either physically or racially, the North African race or races which formed the indigenous substratum in the ancient Egyptian. Indeed, so long as M. J. de Morgan hesitates to apply the term Libyan to the predynastic Egyptians, less well informed mortals should hesitate before doing so.

The second chapter of the work gives a number of general observations on the Berbers, and we may remark in passing that the criticisms made by the writers on the Arabs show that they know little or nothing of the greatest branch of the Semitic race; nothing but youth and ignorance and prejudice can be pleaded in extenuation of them. We confess at the outset that we have no faith in the judgment, not to say scholarship, of writers who intrude personal opinions of the kind in a work which professes to be scientific. Chapter iii. deals with the political and social organisation of a Berber people, and chapters iv.-vi. with the Shawîya people and their manners, customs, &c.; the section on pottery is very interesting. Three chapters (vii.-ix.) are devoted to the description of the Kabâ'il, their country, houses, industries, &c., and this is followed by a dissertation wherein the "New Race" and Kabyle pottery are compared; the writers think that the modern Kabyle pottery is a survival of ancient Libyan pottery, and that because it is almost identical with that of pre-dynastic Egypt there must have been a close connection between the two countries in the most ancient times. There is a good deal of guessing in argument of this kind, and their assertion that the "hieroglyphic language is Semitic" is as bold and just as true as the criticisms of the writers on the Arabs and their character. They do not make this assertion except on the authority of Dr. Erman, who is a good Egyptian scholar, but then Dr. Erman is not a Semitic scholar in any sense of the word, and he has never shown that he has any competent knowledge of *any* Semitic language; on the other hand, Semitic scholars who have studied Egyptology *ad hoc* declare that the old language of the hieroglyphic inscriptions is not Semitic, and until we see further proofs adduced we shall hold that the Semitic scholars are right.

The chapter on rude stone monuments in Algeria summarises a good deal of general information obtained by the writers and others, and it is interesting to note that

Messrs. Randall-Maciver and Wilkin think that the burial practice of the Libyans links them to the early European races and to the Amorites of Syria; but it isolates them completely from the inhabitants of Egypt of any period, whether early or late. Moreover, they assert, as the result of their craniological investigations, that connection of culture gives little or no ground for inferring identity of race between the Egyptians and Libyans; and although they admit that the prehistoric Egyptians—by which they mean the Egyptians of the first three dynasties!—were a mixed race, they declare in no uncertain voice that this mixed race as a whole was not Berber. This conclusion is based on the difference between the cephalic index of the Egyptians and that of the Berbers, and is supported by a number of carefully constructed tablets drawn up on a system which we think is new. The supporters of the theory that the Egyptians were of Libyan origin will be somewhat disturbed by such deductions, but the last word on the subject has not yet been spoken, and it must be frankly admitted that such ingenious arguments and speculations as those set forth by such industrious writers as Messrs. Randall-Maciver and Wilkin only serve in the end to show the general reader how very little is really known about such remote times as those to which they relate.

"Libyan Notes" is an interesting book, not so much for the conclusions arrived at by the authors as for the facts and references to the works of older writers, and the plates contained in it. The "notes" are brightly written, and, as we should expect from Oxford men, some attention has been paid to the style of the English used in their composition. Unfortunately, they do not advance our knowledge of the difficult subjects discussed, and it is hard not to feel that the writers have unconsciously tried to make their facts "square" with too many theories about the origins of civilisation in Southern Europe and Northern Africa. A little more attention might have been given with advantage to the Arabic words and names, especially if quantities are marked; spelling like Hâjji (p. 7), Djemâa (pp. 18, 19), Oukil (p. 20), Zaouïa (p. 21), &c., disfigure the book.

OLD WEATHER RECORDS.

Meteorologische Beobactungen vom xiv. bis xvii. Jahrhundert. Mit einer Einleitung. Herausgegeben von Prof. Dr. G. Hellmann. Pp. 127. 4to. (Berlin: A. Asher and Co.)

THIS volume is the thirteenth of the series of reprints of texts and charts concerning meteorology and terrestrial magnetism published in Berlin under the editorship of Dr. Hellmann. The editor's previous achievements in the bibliography of meteorology are so conspicuous that it will not surprise any one to find that he has selected and arranged extracts from the earliest regular meteorological records in such a way as to produce a most interesting volume. His investigations have incidentally led to considerable additions to our store of knowledge of the meteorology of Europe during the centuries referred to, for inquiry among the libraries has proved the existence of a number of useful weather registers in the margins of old calendars. These doubtless owe their origin, as Dr. Hellmann suggests, to the curious combination of the dearness of paper and the prevalence of the notion of referring weather changes to astronomical causes not exclusively solar, a notion not even yet quite extinct. The index of meteorological observations in the fifteenth, sixteenth and seventeenth centuries accordingly occupies as much as twenty-six pages and becomes an important work of reference for the study of secular changes of climate.

The selection of extracts is thoroughly cosmopolitan. By the exercise of a little ingenuity Dr. Hellmann manages to include with the extracts from observations made in all parts of Europe, in America and on the seas, some information about the meteorological observations of the Chaldeans lately brought to light by Mr. R. Campbell Thompson's publication of the reports of the magicians and astrologers of Nineveh and Babylon. He has something to say too about Theophrastus' book of the winds, which has been translated by Mr. J. G. Wood, and also about some early rainfall measurements in Palestine on the authority of the Mishnah.

The extracts themselves begin with a weather journal for 1343, written in Latin by William Merle, of Driby (Lincolnshire), preserved in the Bodleian Library, and end with observations made in a voyage to China, A.D. 1700, by Mr. James Cunningham, F.R.S., a ship's log originally printed in the *Philosophical Transactions.* Among the names of other observers are Martin Biem, of Krakau (1502); Aventin, of Munich (1511); Pietramellara, of Bologna (1524); Palomino, of Jodar, Spain (1556); Tycho Brahe (1582); Kepler (1623); Marggraf, Brazil (1640); Campanius, of New Sweden, N. America (1644); the Florentine observers (1655); John Locke, of Oxford (1666); and Robert Plot, of Oxford (1684), who gives the earliest extant diagram of barometric changes. Among the early marine observers are Columbus (1535); John Davis (1506); Francis Drake (1596); Henry Hudson (1608); Abel Janszoon Tasman (1642); Friedrich Martens, an arctic traveller (1671); and Edmund Halley (1699), the first 'modern' writer on the general circulation of the atmosphere, whose observations were made on a special voyage of investigation of the ocean winds in the *Paramour Pink*, a vessel placed at his disposal by King William III.

The book is full of interest not merely historical. In view of the difficulty of consulting the originals for the purposes of inquiry into such questions as the periodicity of weather changes, it seems a pity that the material is not reprinted in full instead of by extract. But such a reprint would form an entirely different kind of book.

The volume, like its predecessors in the same series, is a sort of *édition de luxe*; it is beautifully printed on handmade paper and the facsimile reproductions are excellent.

OUR BOOK SHELF.

Le Coton. By Prof. H. Lecomte. Pp. viii + 494. (Paris: Carré and Naud, 1900.)

THIS is largely a work of compilation, and not the result of original research or experiment. In the first part, the methods of cotton culture and the chemical composition and physical structure of the fibres are dealt with. Comparisons are also made between the properties of different cottons and the uses and applications of the by-products, such as cotton-seed oil and its manufacture. The extent to which cotton is now being grown in the United States forms several chapters of considerable interest to those concerned in the extraordinary development of the cotton industry. The other countries of America in which cotton culture is practised are next referred to, such as Mexico, Brazil and Peru. Egyptian cotton, which is largely esteemed, according to the writer, has been principally developed during the last half of the 19th century.

Allusion having been made to the historical use of cotton in eastern countries, Madagascar and Persia, the cotton-growing districts of Asia are then referred to.

Some interesting information is supplied on the baling of cotton as effected in different countries, and on the principal cotton markets of the world.

In the second part of the book the writer reviews the general history of the development of the various branches of the cotton industry, following with an analysis of the trade and its growth as known in France. Similarly, with the progress in England, Austria and Russia, and the remarkable development in Japan.

The work is purely one for the statistician, only being of indirect utility to those engaged in the manufacture of cotton fabrics, or in any way users of the cotton plant. Still, to those who wish to have a comprehensive survey of the remarkable increase in the culture of the cotton plant in countries widely differing from each other in climate and customs, the book will be found invaluable.

ROBERTS BEAUMONT.

Taxidermy; Comprising the Skinning, Stuffing and Mounting of Birds, Mammals and Fish. Edited by P. N. Hasluck. Pp. 160. 12mo. Illustrated. (London: Cassell and Co., Ltd., 1901.)

THE foundation of this little treatise is a series of articles by Mr. J. Fielding-Cottrill—occupying, it is said, nearly twenty thousand columns—which have appeared from time to time in *Work*, and have been brought into their present form by the editor of that journal. In his preface the editor avoids any mention of the class of workers for whom the volume is primarily intended, and it is not easy to infer this from a study of its contents. Certainly the professional taxidermist, who has at his command works of the class of Mr. J. Rowley's "Art of Taxidermy" (reviewed in NATURE for 1898), has nothing to learn from the present handbook, and it is difficult to imagine in what way the ordinary amateur is likely to be interested in the mounting of animals of the size of a waterbuck (p. 49).

It is not as if the author (or editor) had any new ideas to communicate with regard to the mounting of such mammals. On the contrary, although he confuses his readers with an unnecessarily complex system of measurements to be taken before skinning, he is really far behind advanced modern methods in his system, which bears no comparison with that adopted by many Continental and American taxidermists. Indeed, mediocrity may, in our opinion, be regarded as the leading feature of the book; and nowadays we require something beyond this, at least for those workers who attempt the mounting of big game.

As regards the skinning and stuffing of ordinary birds and the smaller mammals, the methods and descriptions are, in an old-fashioned way, well enough; and had the editor restricted himself to work of this nature not much fault could be found with his attempt.

One thing we are glad to notice, namely, that the author advocates painting stuffed fish in imitation of their natural colours instead of being content with the faded scarecrows still to be seen in some of our museums. Whether, however, the methods, both of mounting and colouring, advocated by him would result in the production of specimens bearing any real resemblance to their living prototypes could be decided only by actual inspection of the work.

R. L.

A Treatise on Electromagnetic Phenomena and on the Compass and its Deviations aboard Ship. Mathematical, Theoretical and Practical. By Commander T. A. Lyons, U.S. Navy. Vol. i. Pp. xv+556. (New York: Wiley and Sons. London: Chapman and Hall, Ltd.) Price 25*s*. 6*d*.

THIS first volume, which is to be followed by a second devoted to ships' compasses, takes a wide sweep over physical science generally. Sound waves, light waves, kathode rays, Röntgen rays and Hertzian radiation are treated in a vigorous popular style, special attention being devoted to the functions of the ether which pervades all space. No preliminary knowledge is assumed, common language is preferred to technical, and much information of quite recent date is given—a notable instance being the information regarding atmospheric electricity obtained by kite-flying. The reader never feels himself snubbed as an ignorant person who must be content with elementary knowledge, but is freely admitted to the most sacred arcana.

On the other hand, little attention is paid to precision in the use of scientific language, and both grammar and logic are sometimes loose. Moment of inertia is spoken of as potential energy, and we are told that the field of a current can be measured in dynes; also that the moment of a magnet and the strength of a pole can each be expressed in dynes. On p. 152 the extraordinary statement is made that a steel magnet of suitable strength suspended by a thread between the poles of an electromagnet sets equatorially. As a matter of historic criticism, the discovery of "the dip" is claimed for Peter Peregrinus, simply because he observed that a suspended needle dipped when held over either end of a horizontal magnet.

About a third of the volume deals with magnetism, especially terrestrial magnetism and the instruments for measuring it—a subject with which the author appears to have much practical familiarity, being, it would appear, the founder of the Magnetic Observatory at Washington.

The Steam-Engine Indicator. By Cecil H. Peabody, Professor of Marine Engineering and Naval Architecture, Massachusetts Institute of Technology. Pp. 153. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1900.)

A USEFUL little treatise, easy to read and understand, and well illustrated. It has some defects. The error due to stretching of the cord is thought to be merely a cutting away of the two ends of the diagram, whereas the whole diagram is altered on account of the continuous change of length of the string as the pulling force alters through inertia of the paper barrel and friction. Again, friction of pencil on paper always keeps the diagram *larger* than it ought to be; the author says that it *reduces* the area. Too much space is devoted to the theory of the planimeter and other matters. The important relationship between natural period and time of revolution of engine is not touched upon.

Progress of Invention in the Nineteenth Century. By Edward W. Byrn, A.M. Pp. vii + 476. (New York: Munn and Co., 1900.)

THE author describes scientific discovery and invention from the point of view of a man familiar with the American patent office. Henry, and not Sturgeon, is therefore the inventor of the horse-shoe electro-magnet; Morse, and not Cooke, is the inventor of the telegraph. He has the patent office official's knowledge of science. He bursts into rhapsody only at the beginning and ending of chapters. He gives in each chapter bits of the history of an industry, not very satisfying because very incomplete. But each chapter is readable, being somewhat like an article in an illustrated magazine intended for general readers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Vitrified Quartz.

I THINK Dr. Joly has misunderstood the abstract of my lecture. It is impossible not to feel confident that a transparent solid which has a very low coefficient of expansion, which expands very regularly up to 1000° C. and returns very exactly to its original volume when it is re-cooled, which remains unfused at 1500°, and which bears great and sudden changes of temperature with impunity, must, in the absence of any other really satisfactory material, prove very useful in its applications in thermometry.

The fact that "quartz fibres" are spoilt when they are reheated was well known before Dr. Joly read his paper on the subject. I believe it was first observed by Mr. Boys, and it is more than once referred to by Mr. Threlfall in "Laboratory Arts" (see pp. 116 and 119); but I do not find that vitreous silica in larger masses is equally sensitive, provided that it is protected, when hot, from the action of basic oxides; in contact with these it quickly becomes rotten when heated. This last fact suggests an explanation of the defect observed in the fibres. "Quartz fibres" are spun from vitreous silica in the plastic state when it is in contact with air which teems with dusty particles the dimensions of which are by no means negligible in comparison with those of the very attenuated fibres. Therefore it seems not unlikely that the fibres consist of less pure silica than larger masses of the material.

Those who work in silica should take care to use Brazil crystal as free as possible from alkali, for its melting point and other qualities may be expected to depend largely on its purity, and rock crystal from all sources is not equally pure.

Clifton, Bristol. W. A. SHENSTONE.

A Raid upon Wild Flowers.

IN the last number of NATURE (p. 118) you quote with approval the field studies in natural history, of which the Essex Technical Instruction Committee has issued a programme. I will ask space to state the grounds which lead me to regard this programme as an injury both to natural history and to education.

The teachers of Essex are invited to make a systematic raid upon our wild flowers, and especially upon such as are tending to extinction. They are to collect, name and dry, not only single specimens, but duplicates for "special fascicles." Local guides are to direct them to the last retreats of the rare plants of the New Forest. Nothing is more to be desired, in my opinion, than that the party may fail to discover the things which they most covet.

This eradicating scheme is utterly useless for scientific and educational purposes. There is no science in all this drying and naming. It is enough to condemn the programme as an educational project that novices, knowing little or nothing of field-botany, are set to study the subspecies of brambles! Two pages (14, 15) contain promising headings, but if the work is to be carried out in the spirit of the rest of the programme, this too will end in nothing better than schedules and fascicles and names.

I should be delighted to learn that the Essex Technical Instruction Committee had abandoned the whole scheme as destructive and educationally barren. L. C. MIALL.

P.S.—I have just been assured (June 4) that only advanced students will be allowed to see the rare plants of the New Forest; it is not stated whether they will be allowed to gather them. There was no such restriction in the printed programme. My other objections remain.—L. C. M.

THE programme criticised by Prof. Miall is unofficial so far as the Essex Technical Instruction Committee is concerned. It was not considered by the Committee or by any sub-committee before publication. It is needless to say that, although I am myself a member (co-opted) of the Committee, I am thoroughly in accord with the general spirit of the above criticisms. On carefully considering the programme in detail I am, however, bound to point out that there are several misconceptions in Prof. Miall's letter. The programme was drawn up by the Staff Instructor in Biology, Mr. David Houston, and he is alone responsible for its contents. He will, I am sure, be able to give a satisfactory explanation concerning many of the charges brought against his scheme. My only object in availing myself of the courtesy of the Editor is to remove the impression that the programme is officially authorised by our Committee.

R. MELDOLA.

The Reported Earthquakes in the Channel Islands and South Devon on April 24.

IN a recent letter to NATURE, the Hon. Rollo Russell refers to some supposed earthquakes felt along the coasts of the English Channel on April 24. As accounts of them have also appeared in several London and provincial papers, it may be worth while to state briefly the results of my inquiries.

The disturbances bear a strong resemblance to those caused by the firing of distant heavy guns. Between about 1 and 1.45 p.m. five shocks were felt in Guernsey, and eight at Paignton in South Devon. They were of very short duration; windows were shaken, but there was no perceptible tremor of the ground. Observers in Guernsey compared the sounds to thunder or the firing of very heavy guns; but those on the English coast seem to have been generally unconscious of any sound. Yet the impression of an observer at Salcombe was that a cannon had been fired to the south, but "too far away to bring the noise."

Trials with heavy guns are said to have been made along the coast of France on April 24. I have not succeeded in ascertaining the place or time of the firing; but that the report assigns a possible cause of the supposed earthquakes will, I think, be evident from the above account. CHARLES DAVISON.

Birmingham, May 29.

Foreign Oysters acquiring Characters of Natives.

MAY I call attention to some curious facts with regard to oyster culture? I do not know whether the evolution they undergo is brought about by Lamarckian factors, or whether it is brought about by natural selection, but no doubt a correct interpretation could be given by some of your readers.

The facts are as follows:—Oysters of the species *Ostrea edulis*, one year old, are brought from Brittany, in France, and transplanted at Hayling Island. After two years on the Hayling beds they are transferred to Whitstable. While they are at Hayling they acquire the characteristics of flavour, and texture and colour of shell of the oysters native to Hayling, yet they are distinguishable as originally from Brittany. When they are transferred to Whitstable they acquire the characteristics of Whitstable, yet they are distinguishable as originally from Hayling and Brittany, and are quite distinct from oysters native to Whitstable. Sometimes they have been brought direct from Brittany and laid at Whitstable for three or four years, and, although all the new growth they acquire is characteristic of Whitstable, yet they are distinct from Whitstable natives, and can be easily detected by experts.

Now the curious point is this: these oysters are known to spawn at Whitstable, yet oysters "spat" from this spawn have never been found. There are found, however, especially the last few years, immense quantities of oysters which resemble the ancient native oysters of Whitstable, and are declared by experts to be Whitstable natives, yet differing from them slightly in coarseness of shell and greater growing power, and in being more susceptible to cold weather than the ancient Whitstable natives. Amongst oyster experts these oysters are considered to be the offspring of the oysters originally brought from Brittany, and this opinion is supported by the fact that when these oysters spawn at Hayling the spat from them resemble in every way the oysters native to Hayling. Can the oysters that become changed in this way be considered to have acquired their new characteristics by Lamarckism or by natural selection?

London, May 22. J. M. TABOR.

The Cape Viper.

TO-DAY the Cape viper (*Causus rhombeatus*) laid several eggs. The keeper says this has happened before. As Causus is one of the Viperidæ, and as the Viperidæ (except Atractaspis) are, as their name implies, viviparous, or, to be accurate, ovo-viviparous, it would be interesting to know whether this is a freak, or whether the Causidæ are oviparous in their native state.

CLAUDE E. BENSON.

5 Elvaston Place, Queen's Gate, S.W., May 15.

SOME SCIENTIFIC CENTRES.

I.—THE LEIPZIG CHEMICAL LABORATORY.

LEIPZIG is a city which boasts many traditions; it is associated with some of the most distinguished names in nearly every department of intellectual life; and its University justly takes a place among the leading schools of Europe. To us there is a sense of fitness in the thought that the school which produced a Wagner and a Goethe should have numbered among its teachers two men who have left a mark in the history of the development of organic chemistry. These men are Hermann Kolbe and Johannes Wislicenus; both of them famous as teachers and experimenters, and each of them associated with a theory the importance of the effect of which on the growth of their science it would be difficult to overestimate.

Wislicenus succeeded Kolbe in the chair at the University of Leipzig, and Wislicenus still works in the laboratory which was made famous by his predecessor; he is the oldest survivor of that generation of workers who laid the foundations of organic chemistry, and as such and as a mark of esteem by one of his old pupils, his laboratory has been chosen as the first of the present series.

The laboratory in Liebig Strasse, which has been the scene of so many classical researches, was built by Kolbe, who commenced to work there in the autumn of 1868.

His name was already famous in connection with his earlier work on the determination of the nature and chemical constitution of organic radicles, in which he was materially assisted by the researches of Frankland. But it was in Leipzig that his most brilliant experimental work was carried out; it was there there that, in conjunction with Drechsel, he synthesised oxalic acid from carbon dioxide and potassium, and, assisted by Basaroff, obtained carbamide by the interaction of carbon dioxide and ammonia. Among the early achievements which have invested the present laboratory with such historic interest, and entitle Kolbe to a place among the "wahre Bearbeiter," of Berzelius—to whom, indeed, as well as to Liebig, Wöhler and Bunsen, he used to ascribe his inspiration—must be mentioned the synthesis of isosuccinic acid, the production of nitromethane from chloracetic acid, and the famous reaction for obtaining salicylic acid by the action of carbon dioxide upon sodium phenate, in which he disclosed the singular fact that the use of potassium phenate resulted in the formation of the isomeric para-hydroxybenzoate.

Kolbe died on November 24, 1884. He was not mourned by all who knew him, for his pen had made him not a few enemies; his violent attacks on the "Structurchemiker," and his description of Kekulé's theory of the benzene ring as "wilde Phantasien ohne reelle Basis," have become part of the history of chemistry; while his allusion to the since illustrious van 't Hoff in the words "Ein Dr. J. H. van 't Hoff, findet wie es scheint, an exakter chemischer Forschung keinen Geschmack. Er hat es bequemer erachtet, den Pegasus zu besteigen, und in seiner 'La Chimie dans l'espace' zu verkünden, wie ihm auf dem durch kühnen Flug erklommenen chemischen Parnass die Atome im Weltraume gelagert erschienen sind," was almost worthy of Swift himself.

Wislicenus was appointed director of the laboratory in October, 1885, and effected several alterations in its interior to increase the facilities for work. The number of students rapidly increased till it reached the maximum that the building could accommodate; and in spite of the counter attractions of the Physical Chemistry Institute, which was opened in 1871, the popularity of the first laboratory never waned. At the present time there are 174 students working there, of whom 50 are engaged in carrying on research under the direction of Prof. Wislicenus and his assistants.

Before going on to describe the researches which have maintained the traditions of the laboratory, a brief glance at the career of Johannes Wislicenus will assist us in forming some idea of the nature and variety of his experience.

Born in 1835 in Saxony, the son of a pastor, he received his education first at a school in Halle, and then in 1853 at the University of the same town, where he commenced to study science. But those were the years of revolutions, and in the following autumn his father was forced, on account of his political opinions, to fly to America; there the young Johannes obtained an appointment as assistant to Prof. Horsford at Harvard University, and one year later was made lecturer at the Mechanics' Institute, New York, with a laboratory at his disposal.

In 1856 he returned with his family to Europe, resumed his interrupted studies at the University of Zurich, and later on at Halle; in 1860, he "promovirte, and was appointed 'Privat-docent' at the Zurich Polytechnic." In 1865 he was called to the chair of chemistry at Zurich University, and six years later became director of the Polytechnic. The years 1872-1885 were spent as professor at Wurzburg, where he succeeded Ad. Strecker. On the death of Kolbe the vacant chair at Leipzig was offered him and accepted; and there is a curious irony in the thought that his first work there should have been directed towards the extension of the theory of that van 't Hoff whom his predecessor had regarded with such contempt.

The work of Wislicenus has been confined almost entirely to the domain of organic chemistry. He entered the field when the "Radical Theory" of Kolbe and Frankland had taken a firm hold on the minds of the newer school of chemists.

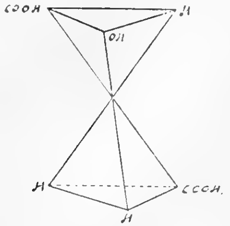
One of the first problems he attacked was the constitution of lactic acid; while still at Zurich he effected its preparation artificially from propionic acid as well as from aldehyde (*Liebig's Ann.* 1863, cxxviii, 11; cxxxiii, 257; and cxlvi, 145). Later on he succeeded in establishing the identity of structure for the two different substances fermentation- and para-lactic acids (*Liebig's Ann. Chem.* 1872, clxvi, 3; and clxvii, 302). The structural theory alone was thus insufficient to explain such cases of metamerism. He was impelled, therefore, even as early as 1873, to the conclusion that the cause of the difference between the two acids must be looked for in the spacial relations of the atoms in the molecule.

But his attention was for a time diverted from this topic by the classical researches which he was carrying out on acetoacetic ether; his chief papers on the subject appeared in 1877 (*Ann. Chem. Liebig*, clxxxvi, 163; cxc, 257; 1881, ccvi, 308). He studied in detail its reactions, mode of preparation and decomposition, and showed it to be the most valuable synthetic agent then known. His work was of the utmost value in throwing light on the still debated constitution of the substance; in it he was assisted by several English students who have since attained eminence.

Wislicenus was now the occupant of the Leipzig chair; after several papers of lesser importance had appeared, he challenged the attention of the world by the publication, in 1887, of the famous memoir: "Über die raümliche Anordnung der Atome in organischen Moleculen." In this he put forward an explanation of what he termed geometrical isomerism, which was an extension of the hypothesis formulated independently by Le Bel and van 't Hoff in 1874. According to this hypothesis "the centre of gravity of a carbon atom was regarded as situated in the centre of a tetrahedron, and its four affinities at the four corners." When two atoms were linked together, van 't Hoff, and after him Wislicenus, assumed that both were capable of rotating in opposite directions about a common axis; this possibility ceased, however, with a double or treble linking of the carbon atoms. Wislicenus further called into play the action of certain "specially directed forces, the affinity energies," which determine the relative positions of the atoms to one another in the molecule.

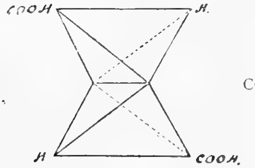
Space will not permit of any detailed discussion of this theory; a single example must suffice to illustrate the manner in which it was applied by Wislicenus.

By heating malic acid to 150° on an oil bath, it is converted almost entirely to fumaric acid; this he explained by the diagrams



= H_2O +

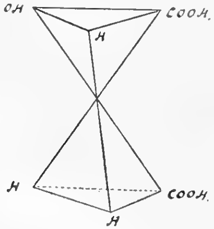
Malic Acid



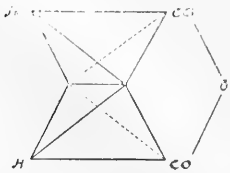
COOH

Fumaric Acid.

If the malic acid be heated from 170—200°, small quantitities of maleic anhydride are formed, though even at this temperature the greater part is converted as before to fumaric acid; this, according to the theory, is due to the existence in the malic acid at the higher temperature of a certain number of molecules in which the atoms have swung round and assumed the positions indicated below; from which the formation of maleic anhydride might be predicted:



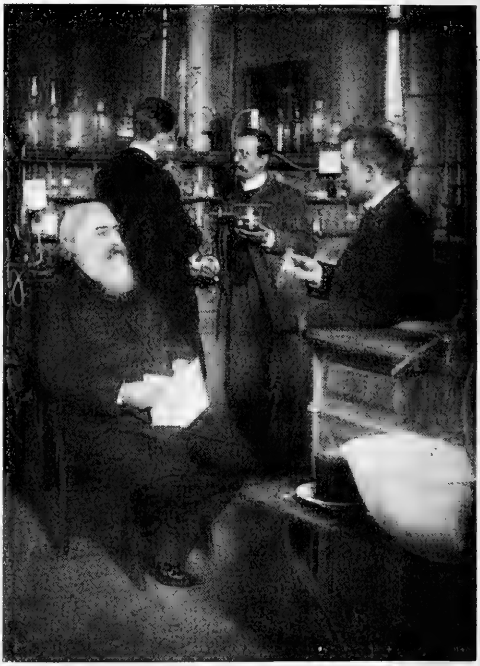
= $2H_2O$ +



Maleic Anhydride.

In the same way Wislicenus applied his theory to all the other reactions of maleic and fumaric acids, to the tolane dichlorides and dibromides, mesaconic and citraconic acids, the crotonic acids, &c; among all the cases he considered, there were only two facts not in consonance with those demanded by the theory; these were (1) the partial conversion of maleic into fumaric acid by the action of bromine, and (2) the production of dibromfumaric acid by the addition of bromine to acetylene-dicarboxylic acid.

In the following year (1888) he published a series of papers (*Liebig's Ann. Chem.* 1888, ccxlvi, 53; ccxlviii, 1; 1889, ccl, 224; cclxxii, 1) containing the results of a large number of experiments (carried out by himself and his pupils) with the object of investigating the nature, constitution and relationships between maleic and fumaric acids, acetylene-dicarboxylic acids, the



Wislicenus in his laboratory.

α-chlorpropylenes, the crotonic acids, the tolane dichlorides, &c.; all of these tended to support the hypothesis he had put forward. In the case of the two apparent exceptions alluded to above, he showed that in the first case the action is far more complicated than at first appears, the conversion of the maleic into fumaric being wholly accounted for by the formation of hydrobromic acid in the course of the reaction, which would suffice to bring about the change. Similarly in the second case, by preventing the formation of hydrobromic acid, the reaction is that demanded by theory, viz., the formation of dibrom maleic acid. Thus the exceptions strengthened rather than weakened the argument.

It is only fair to call attention to the fact that Michael, who has devoted considerable time to the investigation of the subject, has obtained results which in many cases are not explained by the theory of Wislicenus and van 't Hoff (*Journ. Prac. Chem.* 1895, [2], lii, 365–372); but, as was shown in the celebrated controversy with Fittig (*Liebig's Ann.* 1892, cclxxii, 1-99) over the brom-additive products of angelic and tiglic acids, the conditions of the experiment play such an important part in determining the nature of such reactions that the bearing of the results on the validity of the theory must be accepted with a certain amount of reservation. The matter is still the subject of discussion; for the present we can only quote the words of an illustrious chemist, who said that "unter allen sonst vorgebrachten Erklärungs-versuchen lehrt kein einziger auf gleich einfach und gleich umfassende weise die beobachteten Thatsachen verstehen."

Wislicenus has of late been engaged in the application of the theory of spacial relations to the formation of ring compounds, his synthesis of cyclo-pentanone from the calcium salt of adipic acid serving as a starting point in the preparation of the simplest five-ring compounds. Especial interest attaches to the investigation of suberone, which was shown to be a seven carbon ring; for the theoretical consideration of von Baeyer (*Ber.* 1885, xviii, 2277), in addition to those already referred to, would make us regard a seven carbon ring as unstable as a four.

Wislicenus is one of the forty foreign members of the Royal Society, and was awarded the Davy medal in 1898. Still working with all the vigour of an enthusiast, lecturing both in summer and winter at eight o'clock, making frequent tours through the research laboratories with his note-book and cigar, and listening patiently to the "Ausländer" who bury their unsuccessful experiments in the mysteries of the German language, he attracts students of every nationality, for he has a personality which makes its influence felt; and those who have enjoyed the privilege of working under him have lost none of their respect for a distinguished teacher in their appreciation of his kind hospitality and generous spirit.

THE CENTENARY OF THE DISCOVERY OF CERES.

A HUNDRED years have passed since Piazzi, at Palermo, opened a new era in observational astronomy by the discovery of the first of the many small planets that circulate between the orbits of Mars and Jupiter. This welcome, but not unexpected, addition to the known members of the solar system gave an increased interest to the routine of observation, supplied fresh reasons for the preparation of accurate star catalogues, and quickened the researches of practical astronomy, a little overshadowed by the brilliancy of the results won on the physical side by the French mathematicians of the last century. It is true that within the space of time which has elapsed since Piazzi used to such good purpose the altazimuth of Ramsden, the history of astronomy has had to record, not only the growth, but also the decrease, of interest which has been a consequence of the rapid discovery of similar objects. Nevertheless, Piazzi's discovery was fortunate and fructiferous, and we willingly associate ourselves with those of his countrymen who have recently sought to do honour to his memory and to demand due recognition for his services. We are reminded, in a recent number of *Memorie della Societa degli Spettroscopisti Italiani*, that though the story of the discovery of Ceres may have been frequently told and is very well known, yet there are features connected with it of which we may well be reminded. For eight years with untiring diligence did Piazzi patiently work, before he made the discovery which has rendered his name a household word and endeared his memory among his countrymen. Doubtless he himself considered his star catalogue a far greater work, and so posterity will esteem it; but the renown that attaches to such a discovery is immediate and, in a sense, abiding. To appreciate fully what it meant at the time, we must recall the confidence and the agitation which were connected with the so-called Bode's law. The evidence such a formula offered of the existence of an undiscovered planet may not appear now very convincing, but the confidence with which it had been received had been strengthened by the comparatively recent discovery of Uranus, and astronomers, among whom may be reckoned Schrœter and De Zach, were banded together with the firm determination to discover the missing link in the chain of planetary distances. Piazzi, according to Grant, stood outside this company of eager astronomers, but the late Admiral Smyth, who had exceptional information from his personal acquaintance with Piazzi, gives him a place in the circle. In any case it was due to systematic work diligently pursued by the Palermo astronomer that the prize was won.

But, as pointed out by Prof. Angelitti and others who have taken part in the centennial celebrations, the indirect results of the discovery have far outweighed the immediate. Among these may be reckoned the earlier publication of the "Theoria Motus" of Gauss, and especially those chapters which deal with the computation of an elliptic orbit from observations that embrace only a short interval of time. This classical work has remained for a century, the model on which all similar calculations have been based. Alterations of detail have been introduced from time to time bearing upon special parts of the work, but practically the method followed to-day is the method that Gauss evolved to rescue and identify the discovered planet of Piazzi from the stars by which it is surrounded and which it so much resembles. It is well known that Ceres, as the small planet was called, was followed by Piazzi only from January 1 to February 11. Oriani and Bode, to whom Piazzi forwarded his observations, do not appear to have seen the planet in the first year of its discovery, and Gauss' researches and the success that attended them rest entirely on the labours of the original discoverer.

It is not out of place to recall how the discovery of small planets and the eagerness with which they were sought in the middle of last century gave a great impetus to the construction of accurate maps of the heavens. The Berlin charts led to the ready recognition of Neptune, while the ecliptic charts of Hind, of Peters, of Chacornac and of a host of others who engaged in the work, added greatly to our knowledge of the configuration of the heavens and the arrangement of the stellar universe. And it must be remembered that one of the first, if not the first, valuable application of photography to astronomy had for its aim the rapid delineation of such charts originally devised for the detection of small planets. To the fruitfulness that has followed this peculiar direction of thought it is not necessary to refer more particularly, but it would not be difficult to show that the discovery of small planets, originating in the small observatory of Palermo, has exercised an enormous influence on the methods of observation now so generally pursued.

We need do no more here than barely refer to the important part that the group of small planets has played in the oldest of old problems, that of the distance of the Sun. Let the bulky volumes that Sir David Gill has sent from the Cape speak of the work that small planets have furnished to the astronomer in this chapter of his science. And now, practically a century after Piazzi taught us how the space between Mars and Jupiter is crowded with cosmical matter, we find astronomers of all nations cooperating on the systematic observation of one of these small bodies, only intent upon bringing the new material to aid more efficiently in the serivce of the old. Small planets have played, and in the future will continue to play, a part in the onward progress of astronomy, and for this reason we think Italian men of science are well advised to insist upon the recognition of the services of their famous countryman, and they may be assured that all who value solid work diligently performed will give a grateful thought to the unostentatious astronomer of Palermo, who devoted himself with skill and patience to the laborious, and perhaps unappreciated, work of cataloguing the stars. W. E. P.

SYNTONIC WIRELESS TELEGRAPHY.

MR. MARCONI'S lecture on "Syntonic Wireless Telegraphy," recently delivered before the Society of Arts, gives an admirable and most interesting description of the system which he has developed and of the steps by which the development has been effected. "I have come to the conclusion," said Mr. Marconi, "that

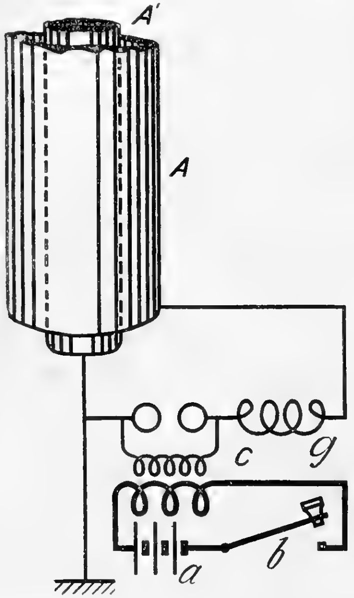


FIG. 1.

the days of the non-tuned system are numbered." If this prophecy be correct the non-tuned system has had, as was indeed expected, but a short life; but even in the few years that it has been in use it has accomplished much, having already to a certain extent greatly increased the pleasure and, above all, the safety of travelling by sea. There can be no better evidence of the general utility of wireless telegraphy than that the time has already arrived when the imperfections of the untuned system are making themselves felt. To quote Mr. Marconi again, "The ether about the English Channel has become exceedingly lively, and a non-tuned receiver keeps picking up messages from various sources which very often render unreadable the message one is trying to receive." That this confusion of messages would sooner or later occur many prophesied in the early days of the art, but few, we think, seriously believed that it would come about so soon. Fortunately, now that the evil is beginning to be felt, Mr. Marconi is ready with the remedy, a well-worked-out and trustworthy system of tuned transmitters and receivers.

The original form of Mr. Marconi's transmitting arrangement is too well known to need illustration: it consisted of an induction coil the secondary terminals of which were connected to a spark gap between two brass balls, one of these being earthed and the other connected to a long aërial conductor. Such a transmitter has a very low electrical capacity, and its radiating power is comparatively great. As a result, the oscillations which take place are considerably damped, and all the energy is radiated in one or two strong swings. Any receiving apparatus in the neighbourhood which is sufficiently sensitive will respond to these radiations even although its natural time of vibration differs greatly from that of the transmitter. Selection of messages with this arrangement is possible, to a limited extent, by using aërial conductors of considerably different lengths and

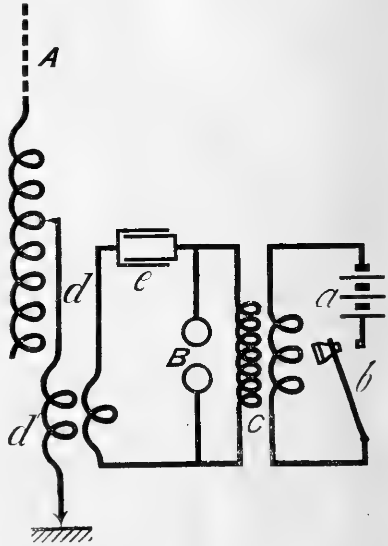

FIG. 2.

by winding the induction coils on the receiving apparatus with the length of wire necessary for correct resonance. But although this answers when the two or more transmitting stations are at different distances from the receiving station, it has been found not to work satisfactorily when the distances are equal.

It is necessary, therefore, to employ some form of radiator in which the oscillations are less damped and which will therefore emit a train of waves instead of one or two strong vibrations. These feebler impulses, falling in succession upon a receiver having the same time of vibration, will get up a swing sufficiently strong to break down the high resistance of the coherer. If, however, the receiver is not in tune, the impulses will not tend to get up any swing, and, being individually too feeble to break down the coherer's resistance, no signal will be recorded. Such a radiator can be constructed as shown in Fig. 1, in which the aërial conductor takes the form of two concentric cylinders, the inner, A', being connected to earth and to one side of the spark gap, and the outer, A, being connected through an inductance, *g*, to the other side of the spark gap. Mr. Marconi finds it essential that the inductance of the two conductors A and A′ should be unequal, the larger inductance being preferably joined to the non-earthed conductor A. Such an arrangement proves both a persistent vibrator and a good radiator, thus enabling selective signalling to be easily carried on over considerable distances with quite short heights of cylinder. Very good results were obtained between the Isle of Wight and Poole, a distance of three miles, with cylinders 1·5 metres in diameter and only 7 metres high.

Another very good syntonised transmitting and receiving system which has been devised by Mr. Marconi is shown in Figs. 2 and 3.

In this the terminals of the spark gap, B, are connected to a closed circuit containing inductance and capacity; such a circuit is a very persistent oscillator, but a bad

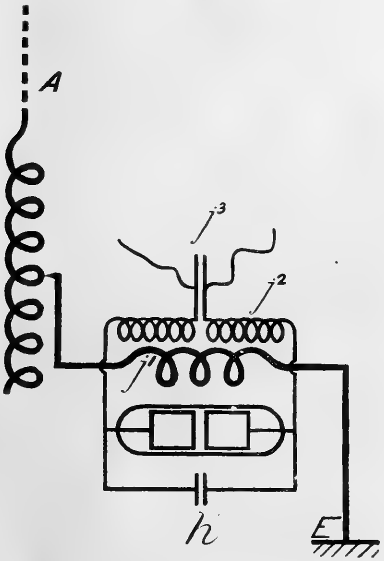

FIG. 3.

radiator and absorber. There is, therefore, combined with it a good radiating circuit, consisting of the vertical conductor, A, which is earthed through an adjustable inductance, *d*. The vibrations set up in the primary circuit connected to the spark gap induce oscillations in the radiating circuit, the mutual action being increased by winding a part of the radiating circuit around the primary circuit (at *d′*), as in a transformer. The two circuits are carefully tuned by adjusting either the capacity, *e*, or the inductance, *d*, or both. In the receiving apparatus (Fig. 3) the connections are similar; the aërial wire is connected to earth through an adjustable inductance, part of which, j^1, is wound as the primary of a transformer of which the secondary, j^2, is connected to the coherer; an adjustable capacity, *h*, is connected across the coherer in order to obtain better tuning. It will be seen that with this arrangement of transmitting and receiving stations there are four distinct circuits, two at each station, which have all to be in tune. Using this system Mr. Marconi has been able to attain very satisfactory syntony even although the same vertical wire be used for the different sets of signalling apparatus, which would be connected to it, in such a case, through inductances of different values.

A still further improvement is effected by combining the two methods described above; in this case the connections are made as shown in Fig. 4, which does not require any further explanation.

Mr. Marconi concluded his lecture with an account of some of the achievements already made with wireless telegraphy. The development has been so rapid under his able guidance that one feels that almost as one writes the systems being described are becoming out of date. Perhaps before long Mr. Marconi will have succeeded, by the use of suitable mirrors and lenses, in guiding the radiation in a definite direction, and thus

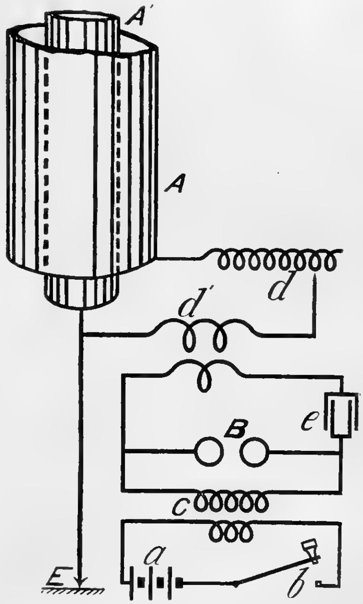

FIG. 4.

have effected a great gain in efficiency. But whether this should prove practicable or not, Mr. Marconi is to be congratulated on the brilliant success of his efforts, and deserves the gratitude of all for having worked out so admirable a system for increasing the safety and convenience of those "that go down to the sea in ships, that do business in great waters."

THE ANTARCTIC EXPEDITION.

TO our great regret the officers of the Royal Society have not yet, so far as we know, made any statement regarding the hopeless condition of affairs which has arisen in relation to the Antarctic Expedition in consequence of the recent action of the Council.

It will be of interest to our readers to observe, in the paragraph we quote below, from *Science* of May 24, the manner in which the management of the Antarctic Expedition is regarded by the scientific men of another nation. The writer has made a natural mistake in supposing that the expedition is under naval control and will sail under naval discipline. This of course is erroneous. The Admiralty has no responsibility and the expedition must be regarded as a private venture. As it stands at present, the expedition is to leave our shores without a man on board who has had any experience in the conduct of a scientific expedition of any importance; and without a commander who has had any experience in the control of a ship. Can the Royal Society bear the onus of responsibility which such a so-called "scientific" expedition will entail upon them?

"Dr. J. W. Gregory, who was appointed scientific leader of the British Antarctic Expedition and as such recently contributed to NATURE a plan of the scientific work, has now stated that he cannot accept service under the regulations laid down. This resignation, for so it has been regarded by the committee, is a very severe blow to the prospects of the expedition, or at least to the scientific results that might have been expected. Some, perhaps, prophesied failure when they saw the attempt that was made from the first to place the expedition under Admiralty control and naval discipline. Friction and consequent heat became inevitable when the committee proceeded to appoint two leaders—a naval and a scientific—without defining their powers from the outset. It is well known that the meetings of this committee have been a series of fights between the geographers and naval men as opposed to the purely scientific men; and Dr. Gregory has over and over again been on the point of resigning. We understand that the ultimate dispute was over the question of landing, which Dr. Gregory wished to have fixed as a main object of the expedition, and not left entirely to the discretion of an unscientific commander. But the actual cause of rupture is immaterial. The position, thanks to the naval manœuvres, has always been an impossible one for the scientific men. While Dr. Gregory's absence in Australia has placed him at a disadvantage, Sir Clements Markham may be congratulated; but the committee will have a difficulty in finding a head for the scientific staff with half the competence of Dr. Gregory."

NOTES.

CAPTAIN E. W. CREAK, F.R.S., has been created a Companion of the Order of the Bath "in recognition of his services while holding the appointment of Superintendent of Compasses in the Hydrographic Department of the Admiralty."

THE Bakerian Lecture of the Royal Society will be given by Prof. J. Dewar, on Thursday next, June 13. The subject will be "The Nadir of Temperature, and allied Problems."

WE regret to see the announcement of the death of Prof. J. Viriamu Jones, F.R.S., principal and professor of physics in the University College of South Wales and Monmouthshire. Prof. Jones was only forty-five years of age.

THE subjects of two of the evening discourses to be delivered during the forthcoming meeting of the British Association at Glasgow have been decided. Prof. W. Ramsay will lecture on "The Inert Constituents of the Atmosphere" on Friday, September 13, and Mr. Francis Darwin will lecture on "The Movements of Plants" on Monday, September 16. As already announced, the lecture to workmen on Saturday, September 14, will be delivered by Mr. H. J. Mackinder.

AN International Congress of Historical Science will be held at Rome in April of next year. There will be a section for the history of science, including especially medical science, and all who are interested in this or other sections of the work of the Congress are invited to communicate with Prof. P. Giacosa, Istituto di Materia Medica, Corso Raffaello 30, Turin.

PROF. WILLIAM GALLOWAY, professor of mining at the University College of South Wales, at Cardiff, has been appointed to investigate on behalf of the Government the cause of the Senghenydd explosion. Prof. Galloway has stated to a correspondent that it was unquestionably a coal-dust explosion, but more he could not say at present. As to the scope of the inquiry, he said specific points had been suggested by the Home Secretary, and the object of the scientific investigation would be to devise means to prevent a recurrence of the accident.

LORD GEORGE HAMILTON has written to Sir Alfred Hickman, M.P., ex-president of the British Iron Trade Association, explaining why certain contracts were placed by Indian railway companies with American firms. In the course of his remarks he says:—"You seem to think that orders have only gone abroad because those who gave them did not understand their business. I wish that it were so. The competition we have to face is founded on something much more formidable and substantial. Chemical research, concentration of capital, thorough technical education, improved industrial organisation have made in recent years greater advance in America than here; it is with the product of these combinations and not with the assumed stupidity of Indian officials that the British engineer has to contend." Sir Alfred Hickman replies in a long letter, which appeared in Tuesday's *Times*, but his remarks refer more to alleged imperfections in American work and the value of protection than to the cause of competition. He asks what evidence exists of "superior chemical research, technical education, &c.," and says, "I deny the 'chemical research'" mentioned by Lord George Hamilton. Apparently Sir Alfred Hickman attaches no importance to such reports as those prepared for the University of Birmingham and the Manchester Technical Education Committee as to the position of technical education in the United States; and he can scarcely be familiar with American scientific and technical publications or he would not "deny the chemical research" with so free a mind. It seems pretty clear, however, that the India Office official who wrote Lord George Hamilton's letter to Sir Alfred Hickman was not the one who expressed views about the chemistry at Coopers Hill and aided the efforts which have strangled the technical education of the officers of the Indian Public Works Department.

THE annual meeting of the Victoria Institute will be held on Monday next, June 10. Sir Robert Ball, F.R.S., will deliver an address.

THE Melbourne correspondent of the *Times* states that Prof. Baldwin Spencer's ethnological expedition, which has arrived at Alice Springs, 1000 miles south of Port Darwin, has obtained valuable photographs of the native war and other dances and sacred ceremonies.

SOLITARY specimens of the Hoopoe are not unfrequently seen on Lundy Island in the spring. A correspondent asks whether any reader of NATURE can explain their appearance or give any information about their nearest abiding place.

WE learn from *Science* that at the recent annual meeting of the American Academy of Arts and Sciences it was unanimously voted to award the Rumford medal to Prof. Elihu Thomson "for his inventions in electric welding and lighting." The Academy has granted to Prof. Theodore W. Richards, of Harvard University, the sum of 500 dollars from the income of the Rumford fund in aid of a research upon the Thomson-Joule effect.

AT the annual meeting of the Institution of Electrical Engineers on Thursday last, it was announced that the council had awarded the following premiums, among others, for papers and communications:—The Institution premium, value 25*l.*, to Mr. M. O'Gorman for his paper entitled "Insulation on Cables"; the Paris Electrical Exhibition premium, value 10*l.*, to Mr. W. Duddell for his paper entitled "On Rapid Variations of the Current through the Direct-Current Arc"; the Fahie premium, value 10*l.*, to Mr. A. C. Eborall for his paper entitled "Some Notes on Polyphase Substation Machinery"; and an extra premium, value 10*l.*, to Mr. J. S. Highfield for his paper entitled "Storage Batteries in Electric Power Stations controlled by Reversible Boosters." Salomons scholarships, value 50*l.* each, have been awarded, one to Mr. J. D. Griffin and one to Mr. H. A. Skelton. The sum of 2000*l.*, bequeathed by the late Prof. Hughes to found the David Hughes scholarship in the Institution, has been received from the executors, and the council has determined that, for the present, the manner of award shall be the same as that of the Salomons scholarship. Mr. C. J. Hopkins has been selected as the David Hughes scholar for the present year, the amount of the scholarship being 50*l.*.

THE celebration of the ninth jubilee of the University of Glasgow will commence on Wednesday next. The following programme has been arranged:—Wednesday, June 12, 10.30 a.m., commemoration service in the cathedral (University officials, guests and delegates are expected to attend in their academic robes or official costume); 2.30 p.m., reception of guests and delegates by the chancellor in the Bute Hall, and presentation of addresses; 8.30 p.m., "at home," Queen Margaret College; 9 p.m., students' gaudeamus in University Union. June 13, 10 a.m., orations in the Bute Hall: Lord Kelvin on "James Watt"; Prof. Smart on "Adam Smith"; followed by conferring of honorary degrees; 3 p.m., opening of the new botanical buildings by Sir Joseph Hooker; 4 to 6 p.m., garden party at Queen Margaret College; 9.30 to 11.30 p.m., conversazione in the Bute Hall, Library and Museum. June 14, 11 a.m., oration in Bute Hall: Prof. Young on "William Hunter," followed by organ recital; 3 to 5 p.m., "at home" in Art Galleries, International Exhibition; 7 p.m., banquet by corporation in municipal buildings; 9 p.m., students' ball in the Bute Hall. June 15, 10 a.m. to 5 p.m., excursion on the Firth of Clyde. Delegates will be present from Austria-Hungary, Belgium, France, Germany, Holland, Italy, Russia, Sweden, Switzerland and from Australia, Canada and India. All the Universities in the United Kingdom will be represented, as well as scientific and other institutions.

THE number of experiments performed on living animals in England and Scotland during the year 1900, under licences granted for that purpose, is given in a parliamentary paper just issued. Mr. G. D. Thane, inspector under the Cruelty to Animals Act, states in his report that the total number of licensees was 247, of whom 63 performed no experiments; that licences and certificates had been granted and allowed only upon the recommendation of persons of high scientific standing; that the licensees were persons who, by their training and education, were fitted to undertake experimental work and to profit by it; and that all experimental work had been conducted in suitable places. The total number of experiments was 10,839, few of which were in any serious degree painful. The experiments performed under licence alone, or under the certificate "permitting experiments in illustration to lectures," together amounting to 1299, were unattended by pain because the animal was kept under an anæsthetic during the whole of the experiment, and must, if the pain was likely to continue after the effect of the anæsthetic had ceased, or if any serious injury had been inflicted on the animal, be killed before it recovered from the influence of the anæsthetic. In 586 additional experiments the operations were performed under anæsthetics, from the influence of which the animals were allowed to recover. The operations were performed aseptically, and the healing of the wounds, as a rule, took place without pain. If the antiseptic precautions failed and suppuration occurred, the animal was required to be killed. These operations as now practised were seldom, if ever, followed by pain. It is stated that in a large proportion of the inoculations the result was negative—that was, the animal did not exhibit any ill effects, and therefore did not suffer any pain. That was especially the case with many inoculations for purposes of diagnosis, with the great majority of the inoculations performed for the testing of articles of food, and with many of the inoculations made for the purpose of standardising antitoxic serum—namely, those cases in which the antitoxin was sufficiently powerful to neutralise the amount of toxin injected, so that the latter had no action. Only a small proportion of the inoculations practised were followed by disease or poisoning.

SINCE the publication in NATURE (vol. lvii. p. 563) of an article upon photographic surveying, much progress has been made in the application of the methods of photography. Valuable information on the subject was given in a lengthy paper on the field-work of photographic surveying as applied in Canada, by Mr. A. O. Wheeler, of the Topographical Surveys staff of the Canadian Government, at the recent London meeting of the Institution of Mining Engineers. In Canada, he stated, the principal surveys upon which the method has been employed are (1) survey of the Rocky Mountains by Mr. J. J. McArthur and Mr. W. S. Drewry, (2) survey in connection with the establishment of the boundary line between Alaska and the Yukon district by Mr. W. F. King, (3) survey of the Alberta watershed for irrigation purposes, (4) surveys in the Yukon district, on the Columbia River and in the Kootenay mining district, and (5) a survey of the Crow's Nest coalfield. The scale upon which the Canadian surveys have been mapped is as follows:—Rocky Mountains survey, 1 to 20,000; Alberta watershed and Crow's Nest survey, 1 to 30,000; Alaska surveys, 1 to 80,000. The larger the scale the greater is the detail required for the drawing. The office work occupies at least twice the time of the field work. To offset this the field work can be accomplished in half the time required for any other method. In the discussion that followed the reading of the paper, Mr. Bennett H. Brough gave particulars of the application of photographic methods to the survey of mining properties in the Carrara marble district, in Mexico and in the Styrian iron ore fields. The rapidity with which the field work was carried out was, he pointed out, a conspicuous advantage in unhealthy malarious districts which a mine surveyor was often called upon to survey.

SINCE the trials of H.M.S. *Viper*, when the wonderful speed of thirty-seven knots per hour was attained, until quite recently further data have not come to hand; but (says *Engineering Magazine* for May) a vessel is now under construction at Dumbarton (Messrs. W. Denny and Bros.) 250 ft. long, 30 ft. beam, and 17 ft. 9 in. depth, which will be propelled by Mr. Parsons' marine turbines, and will be arranged as follows:—There will be three (for going ahead) turbines, each on its own shaft, the high pressure turbine will drive the centre shaft and the two low pressure turbines the two outer shafts. The two "astern" turbines (which propel the ship backwards) are placed inside the exhaust ends of the two low pressure turbines. By this arrangement in going "ahead" steam is expanded five times in the high pressure turbine and again twenty-five times in the two low pressure turbines, giving a total expansion of "125-fold" instead of about "16-fold" which is obtained with triple expansion reciprocating engines. The vessel under construction is for passenger traffic, which necessitates a regular high speed, and there is no doubt that with a ship of this class the best and the most useful results will follow, and not only will she be the pioneer of Mr. Parsons' marine compound turbine in the mercantile marine, but also she will embody all the advantages claimed over ships driven with reciprocating engines, which may be summed up as follows:—(1) Increased speed for the same boiler-power; (2) absence of vibration; (3) increased cabin accommodation (due to the smaller space required for machinery); (4) less upkeep in machinery and smaller engine-room staff. Time alone will prove the increased speed of this vessel and the validity of these advantages claimed over her commercial predecessors.

AN interesting description of the period of activity of Vesuvius in April and May of last year is given by Prof. R. V. Matteucci in the *Bollettino* of the Italian Seismological Society (vol. vi. No. 7), and one of the illustrations accompanying the paper is here reproduced. The eruption commenced on April 24, and lasted a month. There was no lava flow, but the explosions in the crater were very strong, and reached a maximum on May 9, when they were distinctly heard over almost the whole of Campania. The greatest height reached by the volcanic bombs and scoriæ was about 540 metres from the bottom of the crater,

An explosion of Vesuvius in May, 1900

and the largest block ejected had a volume of about twelve cubic metres and a weight of nearly thirty tons. The volume of material thrown out by the volcano during the months of April and May was estimated to have been about half a million cubic metres. For three days Prof. Matteucci remained near the crater of Vesuvius, and on one occasion was fortunate enough to witness an explosion which surrounded him with falling scoriæ and lapilli without injuring him, though the eruption destroyed his photographic apparatus. His observations upon the appearance of the crater during incandescence and the character of the volcanic products are of much interest.

AN aid to the scientific pursuit of photography is afforded by the "Chapman Jones Plate Tester" produced by Messrs. Sanger Shepherd and Co. This new photographic accessory consists essentially of a series of graduated transparencies, a colour sensitometer, and a series of colours—each including one definite region of the spectrum. All these are on one plate and are arranged to show at a glance (1) sensitiveness of ordinary plates, (2) the added sensitiveness of isochromatic plates, (3) the further added sensitiveness of red sensitive plates, this last, being in two parts, distinguishing between the more and the less refrangible than the Fraunhofer line C. The graduated series gives a quantitative value to the colour tests; without it a series of exposures would be necessary, and the result even then would be indefinite. By a single exposure and development the screen gives a quantitative expression of all the properties of photographic plates that are generally of use. Moreover, the record thus obtained can be preserved for more critical examination at any future time, when exact measurement with a photometric arrangement or opacity meter will give results probably as accurate as could be obtained by any method of testing. A plate tester having these joint merits of simplicity and accuracy should prove of service to photographers who base their art upon scientific principles.

"PROSPECTING for Gold in County Wicklow" is the title of a paper by Mr. E. St. John Lyburn in the *Proceedings* of the Royal Dublin Society (vol. ix. new ser. part 4, 1901). The author gives the results of numerous assays of samples of quartz, grit, &c., and in one instance records 4 dwts. per ton from a specimen obtained near the summit of Croghan Kinshelagh. The owner of the estate unfortunately objected to prospecting and Mr. Lyburn had to abandon his work without settling whether or not Wicklow contains gold in payable quantity in the rocks. He observes that panning for gold is secretly carried on in the county and is apparently lucrative to those interested; and he urges further researches on Croghan Kinshelagh mountain, more especially at the junction of the diorite rocks and the Silurian formation.

THE Jurassic Brachiopoda of Cutch form the subject of an important monograph by Dr. F. L. Kitchin (*Mem. Geol. Surv. India*, ser. ix. vol. iii. part 1, 1900). The task undertaken by the author was one not unattended by difficulties, as many years have elapsed since the fossils were collected, and their geological horizons were not in all cases satisfactorily determined. He has, however, received much aid in deciding these matters from Prof. J. F. Blake, who not very long ago personally studied the region. A superficial glance at the plates would lead one to suppose that many British species of Inferior Oolite and Great Oolite Brachiopoda were represented, such as *Terebratula Phillipsi*, *T. globata*, *T. maxillata*, &c.; but although there are forms which appear to show affinity to British species belonging to different Jurassic divisions, yet such forms occur together in Cutch strata, and correlation becomes impossible when the forms on one horizon suggest Bajocian, Bathonian and Callovian ages. Most of the specimens now figured by Dr. Kitchin receive new names, even where the resemblance to a European form is great. This has been done in the belief that the application of the term "variety" is not admissible in cases where the direct relationship to the "species" either cannot be definitely proved or does not appear highly probable. It is satisfactory to learn with regard to Brachiopoda "that to a certain degree, the larger the number of individuals with which we have to deal, the fewer 'species' shall we find them to represent." It would have been better if the author had had the benefit of a series of specimens from a more clearly established stratigraphical sequence, but that he has made the best use he could of the material will not be questioned, and his illustrations are excellent. The fauna as a whole has a distinct facies and is without precise parallel in the European area.

THE Annual Report of the Royal Alfred Observatory, Mauritius, for 1899 has been issued. The chief meteorological feature of the year was the abnormal distribution of rainfall with regard to seasons. The greatest defects occurred in January and December, and the greatest excess in September. The mean rainfall at sixty-eight stations was 76·80 inches, the average amount being 79·23 inches. In possible connection with this we may mention that the deaths from plague were considerable in the months of October to December, following (as in Bombay) the coldest season and an exceptionally wet winter. The report is entirely satisfactory in all respects save one—for want of proper provision for the library, many valuable works are destroyed by rats and other vermin. The director is naturally seriously concerned at this unsatisfactory state of things.

CONSTANTLY increasing attention is being paid to practical entomology in the United States, and we have just received two new parts of the *Bulletin* of the New York State Museum, both of which relate primarily to agricultural entomology. No. 36, vol. vii. (March 1901) contains the sixteenth Report of the State Entomologist on injurious and other insects of the State of New York; and No. 37, vol. viii. (September 1900) contains an illustrative descriptive catalogue of some of the more important injurious and beneficial insects of New York State. These are both by Dr. Ephraim Porter Felt, State Entomologist, and are similar in character to other American Reports which we have recently noticed. We may call attention to two special points in these. The State of Massachusetts seems to be relaxing its campaign against the gipsy moth in despair, and its spread to other States is greatly dreaded. After all the nonsense written in the popular papers about the "kissing bug," it is amusing to find that, according to Dr. Felt, it is neither more nor less than our own wheel bug, *Opsicoetus* (or *Reduvius*) *personatus*, which is common in Europe in outhouses, &c.

THE *Bulletin* of the American Museum of Natural History for 1900 (vol. xiii.) contains an unusual amount of matter interesting to the student of vertebrates, both living and fossil. Some of these papers, such as Prof. Osborn's studies of the European and American fossil rhinoceroses, have been already noticed in these columns, owing to the fact of separate copies having been received. The volume opens with an account, by Dr. J. A. Allen, of the caribou, or reindeer, recently described by Mr. Seton-Thompson under the name of *Rangifer montanus*. The author confirms the distinctness of this form, which is from British Columbia and the North-west Territories, and compares it with other American reindeer, giving a number of excellent photographs of antlers.

IN another communication Dr. Allen gives some interesting notes on the so-called wood-bison of the neighbourhood of the Great Slave Lake, which he considers to be rightly regarded as a distinct race of the species, although it probably once intergraded with the typical bison of the plains. Mr. F. Russell, who hunted these animals in 1894, informed the author that the herd at that time comprised only a few hundred head. "They cannot be hunted in summer," he writes, "as the country which they inhabit is an impenetrable mosquito-infested wooded swamp at that season. . . . They can only be killed by stalking in mid-winter, when their pelage is at its best." This is so far satisfactory, and affords some hope for the survival of the herd, which the Canadian Government is endeavouring to protect. Additional notes on both the reindeer and the bison of the North-western Territories and neighbouring districts are communicated by Mr. A. J. Stone in his report of a collecting trip.

PALÆONTOLOGISTS will find much matter for study in two articles communicated to the aforesaid *Bulletin* by Mr. R. P. Whitfield, the one dealing with certain Arctic fossils collected by the Peary expedition, and the other with the type-specimens of the marine cretaceous lizard described by Cope as *Mosasaurus maximus*. It is inferred that this monster could not have been less than eighty feet in length; portions of the jaws are figured for the first time. Monmouth county, New Jersey, is their place of origin. The Arctic fossils are of Silurian age, and differ in some cases specifically from their representatives in the New York district. In regard to some of the corals, the author writes as follows:—"The specimens are from calcareous clay and are finely weathered, indicating a locality where fine collections of fossils might be obtained with little trouble. The specimens have been collected from the surface and are mostly of small size and imperfect, so much so that those representing undescribed forms are too poor for description and illustration, though sufficient to determine the geological position.

ACCORDING to its Report for the past year, the Zoological Society of Philadelphia has started a new departure in regard to membership which may be commended to the attention of similar bodies at home. This is the admission of junior members, who pay an annual subscription of one pound (five dollars) up to the age of eighteen, when they are eligible for the full membership. In reporting the construction of a new aviary in the gardens, the directors call attention to the reduction which has been found advisable in the size of the cages. This reduction "has resulted from the long experience of the Society in the effort to adjust the needs of animal life to the economical limitations which are forced upon most zoological collections formed upon a large scale. In many groups, as in parrots among birds, and in reptiles of sluggish habit, it has not been found that cages relatively extravagant, both in space and cost, have added observably to health or longevity; in fact, with parrots the best results have been reached in cages too small to induce the attempt to fly." It is added that the public are gainers by the new plan.

WE have received a copy of the *British Central Africa Gazette*, with a supplement containing a full reprint of meteorological observations taken thrice daily at Zomba, during February, 1901. The organisation under which these observations are made is under the direction of Mr. J. McClounie, head of the Scientific Department, and its inauguration has been largely due to the efforts of the British Association Committee on the climate of tropical Africa.

IN the April number of the *Zeitschrift für physikalische Chemie* is a paper by G. Bredig and K. Ikeda, continuing the work commenced by G. Bredig and M. v. Berneck on the "inorganic ferments." It was shown in the first paper that there is a remarkable analogy between the behaviour of a solution of colloidal platinum and the organic enzymes, especially those present in blood. The platinum solution, on account of its perfectly definite composition, lends itself readily to quantitative study, and the results of a very numerous set of determinations of its catalytic power in decomposing solutions of hydrogen peroxide are given. The most remarkable analogy worked out in the second paper is that just as minute traces of certain substances inhibit the catalytic action of the enzymes of the blood, so traces of the same or similar substances act as "poisons" to the colloidal platinum, the quantities necessary in some cases being extraordinarily small. Thus the strongest blood poison is hydrocyanic acid, and this is also the strongest "poison" for colloidal platinum; thus the presence of only 0·0014 milligram of prussic acid per litre was sufficient to reduce the activity of a certain platinum to one-half its original value. Other blood poisons, such as iodide of cyanogen, mercuric chloride, phosphorus and carbon monoxide, behave similarly towards the platinum solutions. There is no doubt that this work will lead to more quantitative studies of the catalytic action of the enzymes proper, the importance of which in both animal and plant physiology is becoming every day more manifest.

SOME of the papers published in the reports and other volumes of the Smithsonian Institution are printed separately for sale or exchange. A classified list of the papers at present available has been issued, and students of all branches of science will find in it many publications of value.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mrs. W. W. Baker; a Red-flanked Duiker (*Cephalophus rufilatus*, ♂) from West Africa, presented by Mr. Th. Leportier; two Crested Curassows (*Crax alector*) from Guiana, presented by Mr. Robert Thom; two Vulturine Eagles (*Aquila verreauxi*) from the Gwatyn District, Cape Colony, presented by Mrs. Joplin; a Derbian Zonure (*Zonurus giganteus*) from South Africa, presented by Mr. W. Champion; a Blue and Yellow Macaw (*Ara ararauna*), a Brazilian Tortoise (*Testudo tabulata*) from South America, a Red-masked Conure (*Conurus rubrolarvatus*) from Ecuador, a Starred Tortoise (*Testudo elegans*) from India, two American Glass Snakes (*Ophiosaurus ventralis*) from Mexico, seven Stink-pot Mud Terrapins (*Cinosternum odoratum*), twelve Pennsylvanian Mud Terrapins (*Cinosternum pennsylvanicum*) from North America, deposited; three Mandarin Ducks (*Æx galericulata*) from China, purchased; a Thar (*Hemitragus jemlaica*, ♂), a White Stork (*Ciconia alba*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE RECENT TOTAL ECLIPSE OF THE SUN.—From the *Comptes rendus* we learn that a French expedition under M. Binot made successful observations at the island of Réunion, near Mauritius, so that very valuable comparisons may be hoped for between these and the photographs obtained at the Royal Alfred Observatory further east.

A telegram from Pulkowa states that during the eclipse at Padang, six photographs were obtained through cirrus clouds, the form of the corona corresponding to that of minimum solar activity.

SNOW ON THE MOON'S SURFACE.—Several accounts have appeared in the daily Press stating that observers from the Harvard College Observatory working in Jamaica have obtained photographs of the moon which afford evidence of the existence of some variable substance, probably snow, on many of the mountain peaks. The astronomer, presumably Prof. W. H. Pickering, has taken photographs of the lunar disc under as varied conditions of lighting as possible during several nights, and the inference now drawn depends on the interpretation of the changes in appearance of the highest tips of the lunar craters. Up to the time of writing no direct confirmation of these observations has been received in this country.

OXFORD UNIVERSITY OBSERVATORY.—The twenty-sixth annual report of the Savilian professor of astronomy to the board of visitors contains an account of the work of the observatory from 1900 May 1 to 1901 April 30. Prof. Turner states that the staple work during the year has been the measurement and reduction of the plates for the Astrographic Catalogue. This has been partly hindered by the building of the new dome and the arrangements for observing the minor planet Eros during its recent opposition, and also the Nova Persei. However, seventy-eight plates have been completed during the year, making a total of 783 in five years, out of the 1180 required. For the Eros determinations 114 plates were obtained, involving 757 different exposures, about half of these having been measured.

The instruments used in India (1898) and Algiers (1900) were taken to Sumatra by Mr. Newall, who will endeavour to make similar determinations with them of the brightness and polarisation of the corona, so that data on a uniform scale from all three coronas may be available for measurement.

All the instruments are in fairly good working order; the new dome by Messrs. Cooke and Sons gives every satisfaction.

THE ROYAL OBSERVATORY, GREENWICH.

ON Saturday last the Astronomer Royal presented his report for the past year to the Board of Visitors of the Royal Observatory. The weather was not all that could be desired on such an occasion, but the rain, which fell later in the afternoon was not sufficiently heavy to mar the proceedings.

Among the numerous guests were M. and Madame Lœwy from Paris.

Below will be found a brief *résumé* of the report:—

Transit Circle.

The sun, moon, planets and fundamental stars have been regularly observed on the meridian as in previous years. The number of transits, the separate limbs being counted as one observation, amounts to 10,938.

The number of stars observed in 1900 is 4787.

The apparent correction for discordance between the nadir observations and stars observed by reflexion for 1900 was found to be $-0''.39$. The results of recent years are as follows:—

	Mean.	Range in Yearly Means.
1880–1885	$-0''.34$	From $-0''.29$ to $-0''.45$
1886–1891	$+0.03$	,, -0.12 to $+0.09$
1892–1900	-0.30	,, -0.25 to -0.41

The New Altazimuth.

This instrument is in good working order, and the new chronograph has worked satisfactorily. Some inconvenience has, however, been caused by breakages in the system of spider lines, which has a larger span than is really necessary.

The instrument has been used during the year mainly as a reversible transit-circle in the meridian in four positions for the better investigation of systematic errors, and for observation of the Eros reference stars and fundamental stars.

Throughout the year 6937 observations have been made, including those for the determination of the chief instrumental errors.

The 28-inch refractor has been used throughout the year for micrometric measurements of double stars.

With the 26-inch Thompson equatorial, the most important work has been the photographing of the planet Eros during the recent opposition for determination of the solar parallax. 255 photographs have been obtained, 197 of which show the planet satisfactorily.

Astrographic Equatorial.

Up to May 10, 682 plates have been taken on 167 nights; 72 of these, for various reasons, have, however, been rejected. In addition to the plates for the chart, 7 photographs were secured for the adjustment of the instrument, two of standard areas, 294 of Eros, 139 of Nova Persei, and 3 of Comet *b* 1900.

The report states that 144 chart plates have been copied on glass, and during the year 81,000 measures of pairs of images (6m. and 3m.), as well as of the diameters of the 6m. images, have been made. The number of plates measured in the twelve months in two positions of the plates is 137.

The measurement of the plates is now completed for 1412 square degrees out of 2087 (which is the area of the Greenwich zone), so that two-thirds of the whole work of measurement has now been done.

Spectroscopic and Heliographic Observations.

With the Thompson equatorial and the photographic spectroscope mounted on it, 22 photographs of the spectra of Capella, Regulus, Arcturus, Spica, α and μ Ursæ Majoris with comparison spectra have been obtained, and some preliminary measures of these give satisfactory results. The spectroscope is now in good adjustment.

For the year 1900, Greenwich photographs have been selected for measurement on 146 days, and photographs from India and Mauritius (filling up gaps in the series) on 214 days, making a total of 360 days out of 365 on which photographs are at present available. The decline in the number of spots noticed in the last report has been continued, and the minimum may be considered as reached, no Greenwich photograph showing a spot since March 7.

Magnetic Observations.

The variations of magnetic declination, horizontal force and vertical force, and of earth currents, have been registered photographically, and accompanying eye observations of absolute declination, horizontal force and dip have been made as in former years.

The regular determinations of magnetic declination, horizontal force and dip have been made with the new declinometer, the Gibson deflexion instrument, and the Airy dip circle mounted in the new Magnetic Pavilion.

The principal results for the magnetic elements for 1900 are as follow:—

Mean declination	16° 29'·0 West.
Mean horizontal force	4·0014 (in British units). 1·8450 (in Metric units).
Mean dip (with 3-inch needles) ...	67° 8' 27".

These results depend on observations made in the new Magnetic Pavilion, and are free from any disturbing effect of iron.

The magnetic disturbances in 1900 have been few in number. There were no days of great magnetic disturbance and eight of lesser disturbance.

The question of the possible effect of disturbances from electric railways on the magnetic work carried on at the Royal Observatory has required very careful consideration in regard to the conditions under which electric traction may be used without injuriously affecting the magnetic registers.

It may be remarked that the French magnetic observatory at St. Maur is in much the same position as Greenwich in respect to electric tramways, and recently M. Moureaux, in charge of that observatory, has found that copper "dampers" (such as have been in use at Greenwich for sixty years, but had not previously been applied to the magnets at St. Maur) reduce the vibratory disturbances from electric tramways to about one-tenth of their amount. This has recently been verified at Greenwich by the converse process of removing the copper "dampers" which are in regular use with the declination and horizontal force magnets, when it was found that the disturbances from existing electric railways were increased to about ten times their amount. It is proposed to apply a "damper" to the vertical force magnet, the need for which has not hitherto been felt, and it is possible that the "dampers" for the other two magnets may be improved by the use of copper of much higher conductivity than was obtainable when they were made sixty years ago.

It is hoped, however, that, in the event of future proposed electric tramways, regulations will be laid down by the Board of Trade to secure adequate protection for the magnetic work at Greenwich, which has now been carried on continuously on the same general system for a period of sixty years, and which could not be transferred to another site.

Meteorological Observations.

The meteorological instruments are all in good order. The registration of atmospheric pressure, temperature of the air, and of evaporation, pressure and velocity of the wind, rainfall, sunshine and atmospheric electricity has been continuously maintained.

The mean temperature for the year 1900 was 50°·5, being 1°·0 above the average for the fifty years 1841–90. During the twelve months ending 1901 April 30, the highest temperature in the shade (recorded on the open stand in the Magnetic Pavilion enclosure) was 94°·0 on July 16. The highest temperature recorded in the Stevenson screen in the enclosure was 91°·8, and in that in the Observatory Grounds 93°·4 on the same day. This is the highest shade temperature recorded in July since 1881. It has been twice exceeded in July in the sixty years 1841–1900, viz., on 1881 July 15, when the temperature reached 97°·1, and on 1868 July 22, when it was 96°·6. A reading of 94°·0 was also recorded on 1876 July 17. The monthly mean temperature for July was 66°·6; it has been exceeded only four times in the preceding sixty years, viz., in 1852, 67°·0; 1859, 68°·9; 1868, 68°·1; and 1876, 66°·7. The month of December was also exceptionally warm, the mean temperature for the month being 45°·7, which is 6°·0 in excess of the fifty years' average. This value has been exceeded three times in the preceding sixty years, viz., in 1852, 47°·6; in 1868, 46°·1; and in 1898, 45°·8. The lowest temperature of the air recorded in the year was 20°·4, on February 14. There were forty-seven days during the winter on which the temperature fell below 32°, a number slightly below the average.

The mean daily horizontal movement of the air in the twelve months ending 1901 April 30 was 298 miles, which is 17 miles above the average for the preceding thirty-three years. The greatest recorded daily movement was 973 miles on January 27, and the least 72 miles on December 23. The greatest recorded pressure of the wind was 34·4 lbs. on the square foot, and the greatest hourly velocity 54 miles, both on January 27.

The number of hours of bright sunshine recorded during the twelve months ending 1901 April 30, by the Campbell-Stokes instrument, was 1513 out of the 4457 hours during which the sun was above the horizon.

The rainfall for the year ending 1901 April 30 was 20·22 inches, being 4·32 inches less than the average of fifty years. The number of rainy days was 151. The rainfall has been less than the average in each year since 1894.

The remaining portion of the report deals with the work done in the remaining departments—namely, chronometer, time-signal, &c. It may be here remarked that arrangements have been made for a re-determination of the Greenwich-Paris longitude in conjunction with observers from the Paris Observatory, two of the four portable transit instruments used in former longitude work being available for the French observers, and the other two for the English.

It has been arranged with M. Lœwy that the first part of the longitude observations shall be made in October next, and the second part in the spring of 1902.

The eclipse of May 28, 1900, was observed by the Astronomer Royal with Mr. Dyson and Mr. Davidson in Portugal, while this year Mr. Dyson, with the assistance of Mr. Atkinson, went to Sumatra, and Mr. Maunder to Mauritius, for the recent eclipse of May 18.

In his general remarks the Astronomer Royal points out the great pressure of work that has fallen on all members of the staff during the past year. Two eclipse expeditions have been prepared and sent out, the revision of Groombridge's Catalogue for 1810, in connection with the Greenwich Second Ten-Year Catalogue (1890), the transfer of books and records to the New Observatory, and the rearrangement of the library and record rooms, all have added considerably to the ordinary work of the Observatory. Finally, he points out that within the last five months one-third of the whole staff of computers have left the Observatory for other posts and have had to be replaced by boys new to their work. Such an extensive change in the temporary staff has, to a certain extent, disorganised the work and has thrown a great strain on the assistants, who are charged with carrying it on under such difficult conditions. Considering the training and experience required in the varied work which, at Greenwich, has to be done by computers, a greater degree of permanence in the staff appears to be necessary for the continued efficiency of the Observatory.

THE MECHANICAL FORCES OF NATURE AND THEIR EXPLOITATION.

THE question of the probable end of the world's coal supply, in the not far distant future, is one which has in recent years been the cause of much discussion. In connection with this subject a pamphlet published by the Urania Gesellschaft of Berlin, on "Die mechanischen Naturkräfte und deren Verwertung," by F. Reuleaux, is of interest. In a clear and popular manner the author traces and explains the gradual utilisation by mankind of the various natural forces, from the ancient Assyrian water wheel to the installations of Niagara, and the Parsons steam turbine. It has been calculated that the supply of coal in England can only last at the most 200 years more; and though the coal-fields of the other European countries have not been used to the extent that the English ones have, still their eventual exhaustion can already be anticipated. The total consumption is now about 600 million tons per year, or, measured as a volume, about 500 million cubic yards. Assuming a yearly increase of 5 per cent. (it is at the present moment greater than this) this would mean that during the present century 6½ billion cubic yards of coal will be taken from the earth's coal mines. A cube of this volume would have a side over ten miles long.

It may be urged that this is not a matter of immediate importance; still, in considering the future industrial state of the world one must admit that great changes must take place, and that countries which have been indebted for their growth to their natural resources of power in the form of coal must give way to those countries where power is supplied in another form. On examining the natural sources of power, one sees that really the only other available source of power besides coal, which, it may be said, can be regarded as the accumulated energy of the sun, stored up through countless ages, is water power. This, unlike coal, is a source of energy which is always with us. The sun piles the waters of the ocean upon the mountain side, and following the force of gravity it flows down again in a never ending cycle, watering, fertilising and, under the careful direction of mankind, rendering the land fruitful and inhabitable and providing for the wants of the human race a source of power immeasurably greater than any power to be derived from the combustion of coal, and what is more, a source of power which will never cease, or be exhausted, while the world lasts. To form a computation of the total energy of the atmospheric depositions is very difficult. It has been calculated to reach the value of 100,000 million horse-power. The realisation of the one-thousandth part of this would be enough to replace the whole of the coal consumption for an incalculable time to come.

An example of how a water power can be used to its fullest extent is furnished by the Upper Hartz. There nearly every drop of water available is utilised, and, although boasting no streams of any size, the respectable total of 3300 horse-power is generated and used in the mining operations carried on there. It is, however, with the advent of electricity that the full realisation of water power has become possible. By means of the facilities offered us by this agent we arrive back at the original motive power of mankind, and will be enabled to tap energies incalculable in comparison with our present ones. This greatest and farthest-reaching application of electricity is but now in its infancy. In 1891, only ten years ago, the first long distance power transmission plant was erected at Lauffen on the Neckar. The power, amounting to 100 horse-power, was transmitted to the electro-technical exhibition at Frankfort on the Maine, a distance of 110 miles, at a voltage of 8000 volts, using a three-phase current. In the short space of time since then immense progress has been made. Now whole towns and large tracts of country are supplied with power and light from distant waterfalls, and new industries have sprung into existence which were formerly impossible. The future developments of this branch of science will be as great, comparatively, as the mighty forces of nature they are designed to employ, and in endeavouring to imagine them the scientific mind merges into the poetic, with which it is, after all, very closely related.

THE COLOUR AND POLARISATION OF BLUE SKY LIGHT.[1]

THE theory of the colour of the sky has been of slow growth. One of the first explanations that we find in scientific literature—almost barbarous in its crudity and unsupported by fact or theory—is the speculation of Leonardo da Vinci that the blue of the sky is due to the mixing of the white sunlight, reflected from the upper layers of the air, with the intense blackness of space. This corresponds to the speculative stage of science, the age of the philosophers. In the next step analogy comes into play; this is a most valuable and effective tool for the man of science endowed with a vivid scientific imagination and with a keen, clear insight into nature, but for others a most dangerous weapon. In this case it is wielded by no less an intellect than that of Sir Isaac Newton. In his optical investigations, about 1675, he had been led to a study of the colours produced when light is reflected from thin films of transparent substances; these he found to depend upon the thickness of the film. When it is very thin it appears black; as the thickness gradually increases it becomes blue, then white, yellow, red, &c. This blue which first appears, and which may be seen surrounding the black spot on soap bubbles, Newton termed the "blue of the first order," and he thought it was of the same tint as the blue of the sky. Analogy now steps in and suggests that the colour of the sky is due to the reflection of sunlight from transparent bodies of such a size that the reflected light is the blue of the first order. This was Newton's belief, and he thought that the reflecting particles were small drops of water.

This is the first theory worthy of serious consideration, and was for a time generally accepted as correct. But no theory based on pure analogy can be regarded as final; it must first be subjected to the most severe analytical and experimental criticism of which we are capable. If it stands the test, well and good; if not, it must be rejected. In 1847 Clausius subjected Newton's theory to a strict mathematical analysis, and proved that, if the blue of the sky is the blue of the first order, resulting from the reflection of light from transparent bodies, these bodies must be in the form of thin plates or thin-walled, hollow spheres. They cannot be solid drops or spheres, for then astronomical objects would never be sharply defined; a star would appear as large as the sun, and the sun immensely larger; all celestial objects would appear as large discs of light, brightest at the centre and fading out gradually toward the edges. For this reason Clausius, believing the blue to be that of the first order, held the opinion that the reflecting bodies were hollow spheres, or vesicles of water. The belief in the existence of so-called "vesicular vapour" did not originate with Clausius, but was a relic which had persisted from the speculative age to this time in spite of its *a priori* improbability, and the natural opposition so caused. As the theory of vesicular vapour has now been completely discarded we need say no more about it; the real value of the work of Clausius lies in the proof that the light from the sky cannot be due to the regular reflection of sunlight from small drops of water.

The experimental test was applied by Brücke, who pointed out that the blue of the sky is radically different from the blue of the first order. Thus, the era of analogy began to give way to that of experimentation and analysis, which must go hand in hand.

Brücke (1853) proved that the light scattered from a turbid medium is blue, and Tyndall (1869) performed his beautiful experiments on this subject, in which he showed that when the particles causing the turbidity are exceedingly fine (too small to be seen with a microscope) the scattered light is not only a magnificent blue but is polarised in the plane of scattering, the amount of polarisation is a maximum at an angle of 90° with the incident light, and the definition of objects seen through it is unimpaired by the turbidity. Here, for the first time, all the essential features of sky light were reproduced in the physical laboratory. This experiment of Tyndall's was at once recognised as giving the key to the problem. Lord Rayleigh (1871–1899) undertook the analytical treatment of the subject and proved that when white light is transmitted through a cloud of particles, small in comparison with the cube of the shortest wave-length present in the incident light, the light scattered laterally is polarised in the plane of scattering, the maximum of polarisation is at 90° to the incident light, and the intensities of the components of the scattered light vary inversely as the fourth powers of their wave-lengths; no account is taken of the light which has undergone more than a single scattering. All these facts have been shown to agree with the phenomena observed in the laboratory when light is passed through turbid media. Recently (1899) Lord Rayleigh has shown that in this way about one-third of the total intensity of the light from the sky may be accounted for by the scattering produced by the molecules of oxygen and nitrogen in the air, entirely independent of the presence of dust, aqueous vapour, or other foreign matter.

We cannot do better than to stop here for a few moments to consider Lord Rayleigh's physical explanation of the scattering produced by small particles. On this theory, light is propagated as transverse vibrations of the atoms or corpuscles of a medium that acts like an elastic solid; it is something like the waves that go along a rope when one end is shaken, only in the case of light we are dealing with no rope but with an infinite medium. When we speak of a beam of light being polarised we mean that all the vibrations in this beam take place in the same plane, and the plane of polarisation may be defined as the plane passing through the direction of propagation of the light but perpendicularly to the direction of the vibrations, and therefore perpendicular to the plane of vibration. Now, imagine a beam of parallel light advancing through a homogeneous medium, say the free ether, in a vertical direction; there will be no light propagated except in this direction; there will be no scattered light. If, however, there exist in it particles optically denser than the ether, but small as compared with the wave-length of light, then light will be scattered laterally by these. Indeed, the effect of these particles is to locally increase the effective inertia of the ether, whereas the rigidity remains unaltered; therefore, when a wave advancing through the medium reaches one of these particles, the displacement of the medium at this point is less than it would be were the particle absent. If we should apply to each

[1] Abridged from an article by Dr. N. E. Dorsey, in the U.S. *Monthly Weather Review*, September 1900.

particle a suitable force (which of course must be in the direction of the displacement and proportional to the difference of the densities of the particle and of the ether) we could restore the amplitude to the value it would have were the particle absent; under these conditions everything would go on as though there were no particle in the ether, and consequently there would be no scattered light, *i.e.*, we should have neutralised the effect of the particle by the application of this force. Hence, on the other hand, we would have the same scattered light if the particle were absent, and we should apply to this portion of the ether this force reversed in direction, that is to say, each particle acts as a centre of a certain harmonic force acting upon the surrounding ether. Such a force will send out a plane polarised wave, whose intensity is symmetrical about the direction of the force as axis; it is zero in the direction of the force, and a maximum in the plane perpendicular to this direction.

The exact effect of such a force has been investigated analytically by Stokes and also by Lord Rayleigh. The displacement in the wave sent out by it is

$$\xi = \frac{F \sin \alpha}{4\pi b^2 D r} \cos \frac{2\pi}{\lambda}(bt - r)$$

if the force is $F \cos \frac{2\pi bt}{\lambda}$; where r is the distance from the centre of force to the point where the displacement is measured; α is the angle between the direction of the force and the line joining the point considered to the centre of force or the mean position of the disturbing particle; b is the velocity of light; D the density of the ether; λ the wave-length of the light sent out by the force; and π is the ratio 3.1416.

If the displacement in the incident wave is $A \cos \frac{2\pi bt}{\lambda}$, the force we must apply to the particle to restore the displacement to its natural value is

$$T(D' - D) A \left(\frac{2\pi b}{\lambda}\right)^2 \cos \frac{2\pi bt}{\lambda},$$

where D′ is the optical density of the particle and T is its volume; therefore,

$$\xi = A \frac{D' - D}{D} \frac{\pi T}{r\lambda^2} \sin \alpha \cos \frac{2\pi}{\lambda}(bt - r),$$

and the intensity of the scattered light is for each particle

$$A^2 \left(\frac{D' - D}{D}\right)^2 \frac{\pi^2 T^2}{r^2 \lambda^4} \sin^2 \alpha.$$

Since the particles are in motion the light scattered from different particles will have no definite phase relation; hence, to get the effect of a cloud of such particles we must add the intensities of the light sent out by each separate particle.

If the incident light is plane polarised, α will be a constant for any given direction from the incident beam, and the total intensity of the light scattered in this direction will be

$$A^2 \left(\frac{D' - D}{D}\right)^2 \frac{\pi^2 \sin^2 \alpha}{\lambda^4} \Sigma \frac{T^2}{r^2}.$$

If the incident light is unpolarised, the intensity of the light scattered at an angle β with the direction of the incident beam will be

$$A^2 \left(\frac{D' - D}{D}\right)^2 \frac{\pi^2 (1 + \cos^2 \beta)}{\lambda^4} \Sigma \frac{T^2}{r^2},$$

where $\Sigma \frac{T^2}{r^2}$ denotes the sum of $\frac{T^2}{r^2}$ for all the scattering particles in the line of vision. In none of this have we taken account of the light that has undergone more than a single scattering. If we denote the mean of the square of $\frac{T}{r}$ by $\frac{T_1^2}{r_1^2}$ and let N denote the number of particles in the line of vision, we can write the expression for the intensity of scattered light in the form

$$A^2 \left(\frac{D' - D}{D}\right)^2 \frac{\pi^2 (1 + \cos^2 \beta)}{\lambda^4} \frac{N T_1^2}{r_1^2}.$$

What are the assumptions we have made in this treatment? They are:

(1) Every scattering particle is so small that when a wave of length λ passes through the medium containing it the force is the same at every point of the particle, *i.e.*, each particle is small as compared with the cube of the shortest wave-length of the incident light.

(2) The particles are so far apart that their effect upon the velocity of light through the medium is negligible; *i.e.* the particles are far apart as compared with the longest wave-length with which we are dealing.

In his discussion of Lord Rayleigh's equations, Crova claims there is a third assumption, viz., that the number of particles in unit of volume must be sensibly the same for all sizes of particles. He says: "La formule $\frac{1}{\lambda^4}$ est basée sur l'hypothèse que le nombre N de corpuscules contenus dans l'unité de volume d'air est sensiblement le même pour toutes les dimensions de ceux-ci." Mascart is of the same opinion. This is evidently wrong. The expression

$$A^2 \left(\frac{D' - D}{D}\right)^2 \frac{\pi^2 T^2 \sin^2 \alpha}{r^2 \lambda^4}$$

applies to particles of *all* sizes, provided they are small in comparison with the cube of the shortest wave-length. The light from a cloud of such particles is merely the sum of the light from the individual particles; the relative number of particles of various sizes does not enter into the consideration at all; indeed, the composition of the light is entirely independent of all consideration of the number and size of the particles other than as specified in the two assumptions we have named. Particles of a size intermediate between these small ones and those larger ones that reflect light regularly produce effects as yet unknown, and are not amenable to this analysis.

From Lord Rayleigh's expression for the intensity of the scattered light we may conclude, if the manifold or multiply scattered light may be neglected:

(1) The scattered light is polarised in the plane of scattering and the amount of its polarisation is $\frac{1}{1 + \cos^2 \beta}$, being a maximum (completely polarised) when the direction of scattering is perpendicular to the direction of propagation of the incident light.

(2) The intensity of the scattered light varies $\frac{1}{\lambda^4}$ times the intensity of the incident light. Its colour or wave-length is independent of the direction of scattering.

(3) The maximum intensity of the scattered light is in a direction almost coincident with that of the incident light and in the opposite direction, and the minimum is in the plane perpendicular to this.

(4) The larger the particles (provided the assumptions above are fulfilled), the more intense is the scattered light.

As stated above, we know little, if anything, about the action of particles that are just too large for this treatment to apply, but in another of his papers Lord Rayleigh has solved to the next approximation (on the electro-magnetic theory) the special case of spherical particles, and finds that the light scattered should vary as the inverse eighth power of the wave-length. In the air there are surely some particles approximately fulfilling these conditions, and hence the sky should appear bluer than indicated by the simple theory we have just considered. But we have not yet bridged the gap between "very small" particles and those large enough to give regular reflection.

We have thus far neglected the multiply scattered light, but this increases in intensity as the square and higher powers of the number of particles per unit volume, while the once-scattered light increases as the first power only. Hence, for a cloud of particles the multiply scattered light may easily become appreciable. This again increases the proportion of the blue.

For all these reasons the colour of the light from the sky should be expressed by the sum of a series of terms of powers of the reciprocal of the wave-length; not by a single term, as is ordinarily attempted. Crova, endeavouring to express the intensity by a single term of the form $\frac{k}{\lambda^n}$, found values of n varying from 2 to 6 under different conditions, the average being about 4, as Lord Rayleigh and Captain Abney had found. But in no case could n be determined so as to give more than a fair agreement. As we have seen, values of n higher than 4 are to be expected; the lower ones are to be accounted for by the lateral scattering caused by the particles between the observer and the source of the scattered light which reaches him, by the absorption of the short waves by interposed water vapour and by the admixture of white light reflected from the larger particles.

The scattering to which we have been referring is evidently different from what we ordinarily mean by reflection; the latter assumes that the reflecting surfaces have an area large as compared with λ^2; whereas scattering assumes that the volume of the particle must be small as compared with λ^3.

Such is in outline the theory and the main facts in regard to the cause of blue sky light; but there are several secondary features which must be now considered. The sky is bluer in the zenith than elsewhere, evidently because the path traversed by the scattered light is here the shortest, so that it suffers less admixture with white light and less absorption of blue light. Conversely it should be less blue near the horizon, and when the sun is low may take on a red or orange tint, as we know is the case. The light from the zenith is most intense when the sun is nearest it, as at true noon, and its blue is least pure at the hottest part of the day, on account of the maximum amount of large particles of dust and vapour constituting the haze existing at this time.

Arago discovered that there is a point, about 15° above the point diametrically opposite the sun (the antisolar point), where the polarisation is zero; between this and the horizon the polarisation is horizontal. Babinet discovered a similar point above the sun, and Brewster found one below it. Between the neutral points discovered by Babinet and by Brewster the polarisation is horizontal; below Brewster's point and above Babinet's it is vertical. For a little way on each side of the neutral points the plane of polarisation is inclined at about 45° to the vertical. This seemed to indicate that superposed upon the polarisation resulting from the scattering of direct sunlight is a horizontal polarisation due to some secondary cause. It was soon suggested that the horizontal polarisation is due to a secondary scattering of the light coming from the lower layers of the atmosphere, and this has generally, but not universally, been accepted as the most probable explanation. Other neutral points have been observed under rare conditions.

The positions of the neutral points, the amount of polarisation, the position of the point of maximum polarisation, as well as the colour of the sky, are intimately connected with other meteorological phenomena, but as yet the observations have been so meagre, made under such dissimilar conditions and by such various forms of apparatus, that it is nearly impossible to tell what is the true connection.

Cornu says—in words of which the following is a translation—"In a general way, the amount of polarised sky light is connected in so direct a manner with the condition of the atmosphere that I have been led to think that it is characteristic of the state of the atmosphere. The greatest clearness of the sky corresponds to the greatest amount of polarisation; cirrus and fog decrease the amount, and even completely destroy the polarisation when the sky is overcast. . . . What is particularly interesting is that the least change in the state of the atmosphere is plainly shown by the polarimeter several hours before other precursory phenomena (barometric variation, halos and various other optical phenomena) have begun to indicate a change.

"Under these conditions it would be useful to carry out these observations in a methodical manner, and to compare the polarimetric variations with other elements characteristic of the atmospheric condition. . . . The amount of polarisation increases as the sun sinks below the horizon until it reaches a certain maximum, after which the polarisation rapidly disappears. The law of this increase of polarisation with the time is very important, for it appears to me to give the vertical distribution of fog in the atmosphere; indeed, if the increase is rapid the lower layers are foggy and the upper ones transparent; if the increase is slow, the atmosphere is more homogeneous."

In short, the more fog or cloud there is present the less the amount of polarisation and the less pure is the blue of the sky.

The most extensive series of observations are those of Rubenson and of Brewster on the polarisation, and of Crova and Abney on the colour of the light from the sky. The first limited himself to observations made in fairly clear weather, and the second directed his attention principally to the determination of the positions of the various neutral points. Rubenson and most other observers have laid special stress upon the intensity of the polarisation at its maximum point in the vertical circle through the sun. This is undoubtedly the point where observations can be most easily taken, and those so obtained must be of great meteorological value; but the interpretation of them is rendered difficult by the variation in the length of the path of the scattered light at different times of the day. At sunrise and sunset the point observed is the zenith, and the path is a minimum; while at noon, if the observer be in the tropics, the point observed may be on the horizon, and the length of the path a maximum. For other positions on the surface of the earth the variation in length of path is less than this.

On the other hand, unless we observe a point of maximum polarisation the observations will be vitiated by every error in determining the position, with respect to the sun, of the point observed. Though other objections may be urged, it has occurred to me that for meteorological prediction the most valuable data would be obtained from continuous observations of the amount of the polarisation of the light from points of the sky on the horizon and 90° distant from the sun. These are points of maximum polarisation; these observations will give a kind of integration of the atmospheric conditions over a large area, and the length of path being the same at all times the observations should all be comparable, except for the varying angle of illumination of the surface of the earth, which, unless the nature of the surface differs greatly in different directions, I think would hardly affect the results appreciably, except, perhaps, when the sun is near the horizon. No one, to my knowledge, has carried out such a series of observations, hence the suggestion is advanced with great hesitation.

Since the colour of the sky is independent of the angular distance of the point observed from the sun, being a function of only the state of the atmosphere and the thickness of the stratum observed, there is but little choice in the altitude of the point where we make the colour observations. But since the blue is a maximum in the zenith this is rather to be preferred, for a slight error in the position of the point observed will here produce the least effect.

Whatever point or points are observed, the fact remains that careful observations on the colour and the polarisation of the light from the sky will give us data determining the amount and size of the particles floating in the air, be they dust or water, and, as any change in the state of the atmosphere will affect these quantities, such observations should be of ever-increasing importance to meteorology. First, however, we must have a long series of observations taken at different places and under all conditions, with exact meteorological data obtained at the same time and place, together with a description of the nature of the surrounding country. When these have been obtained it should be not very difficult to find means of using future observations with great success.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Senate of the University of Dublin has decided to confer the honorary degree of D.Sc. upon Prof. W. Burnside, F.R.S., and Mr. W. E. Wilson, F.R.S.

ON Tuesday, June 18, Lord Avebury will open an exhibition of students' practical work, executed in connection with the technological examinations of the City and Guilds of London Institute, at the hall cf the University of London.

THE Report of the Council of the City and Guilds of London Institute upon the work of the Institute during last year refers to a number of noteworthy matters. The Institute has been incorporated by Royal Charter, but the general constitution remains unchanged. The Central Technical College has become a School in the Faculty of Engineering of the University of London. The Departmental Committee appointed to consider "the best means for coordinating the technological work of the Board of Education with that at present carried on by other educational organisations" has had several meetings, and it is hoped that arrangements may be made for the more intimate association of the work of the Institute's Technological Examinations Department with that of the Board, by which the overlapping of examinations may be avoided and the instruction provided by county councils and technical schools may be brought into closer relationship with the Board of Education and the Institute. Referring to the extrance examination and the teaching of science in secondary schools, the Council remarks: "The Central Technical College is the only college of the University in London which imposes such an entrance test for engineering, and unless and until the University is prepared to adapt its matriculation to suit the requirements of particular classes of students, which it is empowered to do under the new Statutes, and especially to engineering students, no very general or substantial improvement can be expected." Appended to the Report is an address given by Prof. Armstrong upon his retirement from the office of Dean of the College, his term having expired, and an address delivered by Sir Alexander R. Binnie at the opening of the current session. Both at the Central Technical College and at the Finsbury Technical College there was an increase in the number of students in the electrical departments, owing possibly to the development of electric traction in this country.

The president of the Massachusetts Institute of Technology, in his annual report, records that there were in the Institute at the end of last year no less than 1277 students—the largest number yet reached. Of this number 193 were fourth-year students. The average age on entrance is eighteen years and ten months, which is a few months more than the average age at which students enter the Central Technical College, London. An increasing number of students remain for a fifth year or enter the Institute for post-graduate courses. There are thirteen courses extending over four years, and including such subjects as chemical engineering, sanitary engineering and electrochemistry. In looking through the "Annual Catalogue" containing the outlines of the work done in these courses, we are reminded of the statement made in connection with the recent dismissals at the Royal Engineering College, Coopers Hill, that Indian engineers only need to know chemistry "to the extent required to enable the engineer to interpret results given by professional chemists." This is not the way in which engineers are trained at the best technical colleges in the United States, and if Lord George Hamilton and the Board of Visitors of Coopers Hill had seen the programmes of the engineering studies at the Massachusetts Institute they might have decided upon a more liberal action with regard to the subjects to be taught and the provision for teaching in a college where engineers are trained for the public service. The Faculty of the Massachusetts Institute has decided to discontinue the announcement of the degree of Doctor of Science, and to make the requirements for the degree of Doctor of Philosophy include "high attainments of a grade which qualifies the recipient as a scientific investigator and teacher." During 1900 the Institute received 100,000 dollars (less succession tax) under the will of the late Mr. R. C. Billings. The gift of 50,000 dollars by the late Mr. A. Lowell to constitute "The Teachers' Fund" has been increased to 100,000 by the executors, in conformity with his wishes. Other gifts received during the year amount to about 45,000 dollars. The total amount of the Institute property, both real and personal, was increased during the year by a net amount of 219,853 dollars, after deducting the sum of 8593 dollars, which is the excess of expenses over income.

SOCIETIES AND ACADEMIES.

London.

Royal Society, May 23.—"A Comparative Crystallographical Study of the Double Selenates of the Series $R_2M(SeO_4)_2,6H_2O$—Salts in which M is Magnesium." By A. E. Tutton, B.Sc., F.R.S.

This memoir on the magnesium group of double selenates, in which R is represented by potassium, rubidium and cæsium, is analogous to that which was presented to the Society in March 1900 concerning the zinc group.

The conclusions derived from the study of the morphological and physical properties of the crystals of the three salts are generally similar to those arrived at from the study of the zinc group. There is observed an uniform progression with regard to every property in accordance with the order of progression of the atomic weights of the three alkali metals present. That is to say, the constants of the rubidium salt are generally intermediate between those of the potassium and cæsium salts.

The magnesium group has, however, proved particularly interesting, inasmuch as the progressive diminution of double refraction, according to the rule which has now been established for this series of double sulphates and selenates, leads in the case of cæsium magnesium selenate to such close approximation of the three refractive indices that the crystals of this salt exhibit exceptional optical phenomena. This includes dispersion of the optic axes in crossed axial planes at the ordinary temperature, the uniaxial figure being produced for wave-length 466 in the blue; and the formation of the uniaxial figure for every wave-length of light in turn as the temperature is raised, the attainment of uniaxiality for red lithium light occurring at the temperature of 94°. As the life-history of the salt terminates at 100°, owing to the presence of water of crystallisation, this substance exhibits the property of simulating uniaxial properties at some temperature within its own life-range for every wave-length of light, while still retaining the general characters of monoclinic symmetry, including slight dispersion of the median lines. In this respect it resembles to a truly remarkable extent the analogous sulphate, which the author has shown to possess like peculiarities, but it is even more striking than the sulphate, as the dispersion is much larger. It is interesting to observe that these optical properties of cæsium magnesium selenate could have been predicted, given the constants of the potassium salt and the rules of progression established for the double sulphate and for the zinc group of double selenates. For the double selenates resemble the double sulphates so closely that in general it may be said that their properties are precisely parallel, the constants and curves being merely moved on to a slight extent by the replacement of sulphur by selenium without disturbing their relationships.

Physical Society, May 31.—Prof. S. P. Thompson, president, in the chair.—A paper on the resistance of dielectrics and the effect of an alternating electromotive force on the insulating properties of india-rubber, by A. W. Ashton, was read by Prof. Fleming. The author has obtained from his experiments formulæ for the charging and discharging currents of a condenser with rubber dielectric. The currents are exponential functions of the time. Curves for various potential differences have been plotted and were exhibited. These curves show that the insulating properties of rubber are increased by the application of high alternating electromotive forces.—Prof. Fleming then read a note by Mr. Ashton on the electrification of dielectrics by mechanical means. A sheet of pure Para rubber was placed in a condenser, the plates of which were connected to a quadrant electrometer. A two-pound weight was then dropped upon the condenser from a height of 3 inches. The electrometer received two impulses of opposite sign, one quickly following the other. The rubber was then stretched while in position and a potential difference of seven volts was shown between the plates, the top plate being negative. The condenser and electrometer were then discharged, the sheet reversed and the experiment repeated. The same effect was produced, the top plate again being negative. It appears, therefore, that polarisation of a dielectric being thus produced by mechanical energy, some part of the mechanical energy expended on the india-rubber during manufacture would remain in the dielectric as electric energy.—A model which imitates the behaviour of dielectrics, by Prof. Fleming and Mr. Ashton, was exhibited by Prof. Fleming. The behaviour of dielectrics with regard to their residual charge is analogous to that of wires subjected to mechanical stress. A simple twisted wire is not, however, able to imitate all dielectric effects, and the present paper describes a model which represents things more completely. Six pistons, separated by springs, are placed inside a vertical cylinder. The bottom piston fits fairly tightly in the cylinder. The second piston fits slacker than the first. The third piston has a small hole in it, and each succeeding piston has a greater area cut away, the top piston having just sufficient metal left to make the spring come to rest without vibration after being compressed. The cylinder is filled with machine oil and vaseline. To the top piston is attached a rod by means of which pressures can be exerted on the pistons for any length of time. This represents the charging of the condenser. The motion of the rod after releasing the weights represents the discharge of the condenser. This is registered graphically by a revolving drum, and the curves obtained are very similar to those from condensers with dielectrics. Prof. Ayrton said he would like to know in what respect the model shown was superior to a strained wire. He had noticed, about ten years ago, that alternating E.M.F.'s appeared to improve condensers. He was then working with comparatively small voltages, and he was interested to know that Mr. Ashton, working with high voltages, had established the improvement. The deflection obtained by stretching the india-rubber sheet might be due to changes in temperature, the dielectric having a high thermoelectric power. Mr. Price was glad that the question as to what actually might be called the resistance of a dielectric had been raised. There are two theories of residual charge, one due to Maxwell and the other to Heaviside. The model exhibited represents Maxwell's theory. He considered that the electrometer experiment with the rubber dielectric favoured Heaviside's theory—that is, that the dielectric is composed of small charged bodies similar to the small magnets conceived to constitute a magnet. He expressed his interest in the fact that the top plate of the condenser was always negative. Mr. Blakesley suggested putting a small hole in the bottom piston of the model so that it might represent a condenser passing a small steady current. With regard to the stretched rubber experiment, he said it would be interesting to make observations with the plates of the condenser vertical. Mr. Campbell said he had made experiments and found that the change in capacity of the rubber condenser affects the voltage sufficiently to mask the real effect. Mr. Appleyard said it was important to have perfect contact between the dielectric and the metal plates. It was pointed out by a visitor engaged in the cable industry that manufacturers are aware that pressure affects the insulating properties of guttapercha. Rubber is a mixture, and different rubbers behave differently under the action of alternating potential differences. The chairman said that if the quantity of electricity taken in on charging was equal to the quantity given out on discharge, then there could be no dielectric hysteresis.

Royal Microscopical Society, May 15.—Dr. R. Braithwaite, vice-president, in the chair.—A paper by Mr. Fortescue W. Millett, being part xi. of his report on the recent Foraminifera of the Malay Archipelago, was taken as read.—Notice was given that on June 19 there would be a special meeting of the fellows for the purpose of making certain alterations in the by-laws.—The secretary announced that at the next meeting of the Society there would be a paper on the aperture theory of the microscope by Mr. J. W. Gordon. Mr. Beck asked any fellows who possessed Abbe's diffraction apparatus to lend them for use in illustrating the subject of Mr. Gordon's paper. Mr. Gordon would endeavour to show that the effects described by Prof. Abbe, and relied upon by him to prove his diffraction theory, were produced, not by the object on the stage, but by the diaphragm over the object glass; to demonstrate this satisfactorily Mr. Gordon would require the use of several sets of diffraction apparatus besides those at his present disposal.—The chairman drew attention to a large number of objects illustrating pond life which were exhibited (under about 35 microscopes) by members of the Quekett Microscopical Club and fellows of the Society.

Zoological Society, May 21.—Dr. W. T. Blanford, F.R.S., vice-president, in the chair.—Mr. Oldfield Thomas read a paper on the more notable mammals lately obtained by Sir Harry Johnston in the Uganda Protectorate. The following species were described as new:—*Colobus ruwenzorii*, allied to *C. palliatus*, but with longer hair and less white on the tail-tip; *Genetta victoriae*, a genet nearly as large as a civet, strongly banded, and without a dorsal crest; *Procavia marmota*, like *P. dorsalis*, but much smaller; and *Cephalophus johnstoni*, like *C. weynsi*, but darker throughout.—A communication was read from Mr. R. C. Punnett containing an account of the Nemerteans collected by Prof. D'Arcy W. Thompson and others in Behring Straits, Davis Strait and North Greenland. Of the seven species enumerated in the paper two had been previously named, whilst the remaining five were new to science and were described as *Amphiporus arcticus*, *A. paulinus*, *A. thompsoni*, *Drepanophorus borealis*, and *Cerebratulus greenlandicus*.—A communication was read from Dr. W. B. Benham containing an account of the viscera of a whale of the genus Cogia. He pointed out that in this whale there is but a single blowhole asymmetrically placed like that of Physeter, but crescentic in outline, with the concavity directed backwards. The alimentary canal contained a dark-coloured substance, which the author considered to be the "ink" from the cuttle-fishes upon which this whale undoubtedly feeds, as was evidenced by the beaks of these molluscs in the stomach. The stomach was constructed upon the plan of that of the large sperm-whale (Physeter), and the author agreed with others in regarding the first division of it as a paunch belonging really to the œsophagus, and comparable with that of the Ruminants.—Mr. G. A. Boulenger, F.R.S., described two new species of chameleon, obtained by Sir Harry Johnston, K.C.B., on Mount Ruwenzori, under the names *Chamaeleon xenorhinus* and *C. johnstoni*.—A paper was read, prepared by the late Dr. John Anderson, F.R.S., shortly before his death. It contained an account of the reptiles and batrachians obtained by Mr. A. Blaney Percival in Southern Arabia. Twenty-five species of reptiles and three species of batrachians, of which specimens were contained in the collection, were enumerated; two of the former were described as new under the names *Bunopus spatalura* and *Agamodon arabicum*.—Mr. Boulenger described a new fish under the name *Gobius percivali*, specimens of which had been obtained by Mr. A. Blayney Percival in Southern Arabia.

Geological Society, May 22.—Mr. J. J. H. Teall, V.P.R.S., president, in the chair.—On the skull of a chiru-like antelope from the ossiferous deposits of Hundes (Tibet), by Richard Lydekker. Twenty years ago the author proposed the provisional name of *Pantholops hundesiensis* for an extinct species of antelope typified by an imperfect skull figured in Royle's "Botany &c. of the Himalaya Mountains," pl. iii. fig. 1. The specimen is in the Museum of the Geological Society, and an examination has confirmed the original determination.—On the occurrence of silurian (?) rocks in Forfarshire and Kincardineshire along the eastern border of the Highlands, by George Barrow (Communicated by permission of the Director of H.M. Geological Survey). These rocks occur in three lenticular strips between the schistose rocks of the Highlands and the boundary-fault next the Old Red Sandstone. The largest is about twenty miles long, and extends almost from Cortachy to beyond the Clattering Bridge; it is about three-quarters of a mile wide at its widest. The rocks are divided into two groups, the Jasper and Green-Rock Series below and the younger Margie Series above. A section along the North Esk River is described in detail, and other sections referred to it. The lower division consists of fine-grained sandstones (bearing microcline), grey slaty shales, jaspers (sometimes containing circular bodies resembling radiolaria), and a variable series of basic igneous rocks ("green rock") of coarse texture and probably intrusive origin. The upper division consists of conglomerates, pebbly grits, dark and white shales, pebbly limestone and grey shale. The age of the series cannot be definitely ascertained, but the lower division is compared with the Arenig cherts, &c., of the Southern Uplands, while the Margie Series is newer than this, but older than the Old Red Sandstone.—On the crush-conglomerates of Argyllshire, by J. B. Hill, R.N. (Communicated by permission of the Director of H.M. Geological Survey.) While the sedimentary origin of the Highland Boulder-bed is proved by the foreign boulders contained in it, there occur in the Loch Awe region certain conglomerates, often along definite horizons, which may have been confused with it, but which the author is able to prove have originated by crushing. The sedimentary rocks of the area include all the members of the Loch Awe series, consisting of grits, slates and limestones, the latter being mostly gritty in character. Associated with these is an enormous amount of igneous material of Dalradian age, ranging from intermediate to basic in composition, together with porphyrite-dykes probably of Old Red Sandstone age, and a plexus of Tertiary dykes.

Linnean Society, May 2.—Prof. S. H. Vines, F.R.S., president, in the chair.—Prof. Charles Stewart, F.R.S., exhibited and made remarks on the egg and oviducal gland of *Scyllium catulus*, and on the nature of the egg-shell of Sphenodon.—Mr. W. P. Pycraft read a paper on the palate of the Neognathæ, in which he traced the derivation of the Neognathine from the more primitive Struthious or Palæognathine palate.—Mr. George Massee communicated a second instalment of his redescriptions of Berkeley's types of fungi, and explained the circumstances in which such redescriptions under higher powers of the microscope had become desirable.

May 24.—Anniversary meeting.—Prof. S. H. Vines, F.R.S., president, in the chair.

Anthropological Institute, May 28.—Prof. A. C. Haddon, F.R.S., in the chair.—Dr. Chervin referred to the proposed bibliography of anthropology and to the exchange of abstracts of *Proceedings*; he further suggested the possibility of a more frequent interchange of visits, offering, on behalf of his Society, to act as cicerone if the Institute would undertake an anthropological excursion in France.—Mr. A. Henry exhibited (1) an ancestral tablet, (2) a MS. of the Lolos of Yunnan.—Mr. J Gray presented a communication on the measurements of crania from the Fly River, New Guinea.—Mr. C. G. Seligmann presented anthropometrical craniological notes on the Eastern Papuans.—Dr. A. C. Haddon discussed the present state of our knowledge of the ethnology of British New Guinea.

CAMBRIDGE.

Philosophical Society, May 20.—Prof. Macalister, president, in the chair.—On the rate of growth of certain corals, by Mr. J. Stanley Gardiner. The author put in a plea for more precise observations on the subject, showing in discussing his specimens the various conditions of life, which he considered necessary to record. It was suggested that the volumes of specimens should be calculated, and that if possible the thickness of each skeleton, imagined as a flat plate covering the same horizontal area as its living colony, should form the basis for comparison. By the latter method the specimens showed, in a growth of less than 1030 days from the larvæ, various thicknesses between 10 and 25 mm.—On the breeding habits of *Xenopus laevis Daud*, by Mr. E. J. Bles.—On the recovery of foliage leaves from surgical injuries, by Mr. F. F. Blackman and Miss G. L. C. Matthaei. It has been found that if definite areas of these leaves be killed by heat or by physical means, the remaining sound tissues divide actively and form an absciss-layer which surrounds the dead cells and cuts out the area so that it drops away from the leaf. Specimens were exhibited showing the stages of this process, which takes place with such precision that leaves may thus be shaped to any desired form.—On a new species of *Bothriocephalus*, by Mr. A. E. Shipley.—On a class of matrices of infinite order and on the existence of matricial functions on a Riemann surface, by Dr. A. C. Dixon.—On liquid motion from a single source, by the Rev. H. J. Sharpe.

EDINBURGH.

Royal Society, May 20.—Prof. Geikie in the chair.—Mr. Alfred Harker communicated a paper on ice-erosion in the Cuillin Hills, Skye, in which evidence was accumulated to show that this region had never been over-ridden by foreign ice, but had supported during the maximum glaciation a local ice-cap. The general radial outflow followed with few exceptions the principal valleys, but on reaching the lower ground was sharply diverted toward the west by the pressure of the great Scottish ice-sheet. The chief part of the paper was devoted to an analysis of the surface relief of the Cuillins, the more striking elements of which were the result of glacial erosion, as distinguished from aqueous erosion. Among these were the general absence of any relation between detailed topography and geological structure; the unbroken extent of the main ridge with its steep flanks and cuspate cross-section, and the tricuspate ground-plan of its principal peaks; the curiously asymmetric form in cross-section of the branch ridges, with the steeper face always toward the north; the straight steep-sided valleys with U-shaped cross-section and abruptly stepped longitudinal profile; and other well-marked characteristics. The drift accumulations were also discussed, stress being laid on the action of ice not merely in grinding down a rock-surface but in tearing away fragments, especially of well-jointed rocks. The maximum glaciation in central Skye was succeeded by a period of valley glaciers; and at the same time the withdrawal of the Scottish ice-sheet allowed an unimpeded out-flow of the ice-drainage from the Skye mountains. At this stage the exposed summit ridges of the Cuillins suffered greatly from frost-action, the detached blocks being in part carried away on the glaciers, in part accumulating in great taluses wherever the head of a valley had become vacated by the dwindling ice.

PARIS.

Academy of Sciences, May 28.—M. Fouqué in the chair.—On the parallax of the sun, by M. Bouquet de la Grye.—The addition of hydrogen to various hydrocarbons, by MM. Paul Sabatier and J. B. Senderens. It has been shown in a previous paper that benzene and toluene in contact with hydrogen and reduced nickel readily form the hexahydro-addition products. It is now shown that this reaction is a general one, similar addition compounds being obtained from a great number of aromatic hydrocarbons. In the case of substituted benzenes in which the side chain exceeds a certain length, a secondary decomposition takes place. Thus ethyl-benzene gives not only the ethyl-cyclohexane, but also methyl-cyclohexane and a small quantity of methane. Propyl-benzene in the same way gives a little methyl-cyclohexane and ethyl-cyclohexane. The yields of the various hydrocarbons are very good, and the physical constants of several of them now prepared for the first time are given.—Observations of the comet A(1901) made at the Observatory of Algiers with the 31·8 cm. equatorial, by MM. Rambaud and Sy. The comet appears in the form of a nebula with a nucleus of a lustre comparable with a star of the 8th magnitude.—On the spectrum of the solar corona photographed at Elche (Spain) during the total eclipse of the sun of May 28, 1900, by M. A. de la Baume-Pluvinel. Five photographs of the corona and its spectrum accompany the paper.—The wave-length of some iron rays, by MM. Fabry and Perot. By the application of the interference method described by the authors in previous papers the wave-lengths of fifteen of the chief iron lines have been determined with an accuracy of six significant figures.—On the density of alloys, by M. E. van Aubel. The aluminium-antimony alloy containing 81 per cent. of aluminium is produced with a large increase of volume, 7 c.c. of aluminium and 12 c.c. of antimony giving 23·7 c.c. of the alloy AlSb.—On a very sensitive balance which is capable of acting either as a galvanometer, electrodynamometer or an absolute electrometer, by M. V. Cremieu. Two small magnets are carried on a small torsion balance composed of two silk fibres. These wires are sucked into bobbins carrying a current, the arrangement forming a sensitive astatic and dead beat galvanometer.—On the reduction of silver chloride by hydrogen, by M. Jouniaux. The interaction of hydrogen and silver chloride at various temperatures above 500° C. is reversible. The experimental results are applied to calculate the difference between the heats of formation of hydrogen and silver chlorides.—Observations on the preceding note, by M. Berthelot.—The action of mercuric oxide upon aqueous solutions of metallic salts, by M. A. Mailhe.

NEW SOUTH WALES.

Linnean Society, March 27.—Mr. J. H. Maiden, president, in the chair.—Description of a new species of Acacia, by J. H. Maiden. The plant described is an erect shrub of several feet from the highest part of the Blue Mountains.—Note on the Subgenus salinator of Hedley, by Edgar A. Smith.—Studies on Australian mollusca, part iv., by C. Hedley. Geological notes on Kosciusko, by Prof. T. W. Edgworth David, F.R.S, Richard Helms and E. F. Pittman. This paper deals with the subject of recent discoveries by the authors in company with Mr. F. B. Guthrie, of ancient moraines, erratics, and extensive rock surfaces grooved by glacier ice on the Kosciusko plateau. Some of the best preserved evidences noticed were in the Lake Albina Valley and in the valley of Lake Merewether (Blue Lake). At the latter locality there is a magnificent and well preserved moraine 400 feet above the surface of the lake, and containing ice-scratched blocks in enormous numbers. A very fine ice-grooved pavement of granite was observed at a point about 300 yards west of the southern end of Lake Albina. There is certain evidence that the glaciers came down, in comparatively recent geological time, to 5800 feet above the sea and probably to 5500 feet at least, Mount Kosciusko proper being about 7328 feet high. It is also clear that the ice in some of these glaciers was at least 400 feet thick. It is quite possible that at a still earlier period the whole plateau down to a level of about 5000 feet was buried under an ice-sheet. The exact downward limit has not yet been ascertained. The comparatively recent nature of the glaciation is shown by the fact that since the ice disappeared a depth of only about 10 feet of loose moraine and a further depth of 10 feet of soft slate have been eroded in the beds of the creeks which form the sources of the Snowy River. The authors consider that this evidence, taken in conjunction with that recently adduced in South America, Kerguelen, New Zealand and Tasmania, suggests a synchronism of glaciations of the northern and southern hemispheres, due to some such cosmic cause as that suggested by Dr. Arrhenius, viz., a slight temporary diminution of carbon dioxide in the earth's atmosphere.

April 24.—Mr. J. H. Maiden, president, in the chair.—Notes from the Botanic Gardens, Part 7, by J. H. Maiden and E. Betche. A number of new species and varieties were described.—Notes on the caves of Fiji, with especial reference to Lau, by B. Sawyer and E. C. Andrews. During their travels in the Fijian Archipelago the authors observed two types of caves—the excavated and the enclosed. Magnificent examples of caves excavated by percolation and subterranean streams occur in Viti Levu. In the Lau group appear the enclosed caves—vacant spaces walled and roofed in by coral growth. In their early stages these are seen in the living reef as precipitous chasms.—Observations on the eucalypts of New South Wales, Part 8, by Henry Deane and J. H. Maiden.—Bacteria and the disintegration of cement, by R. Greig Smith. Stutzer and Hartleb considered that the disintegration of the cement work of water reservoirs might be caused by the action of the nitrifying organisms. The author has investigated a case where the cement work of a water canal was disintegrating. Nitrifying organisms were found in the surface mud, but not deeper into the cement where disintegration was in active progress. The nitrifying bacteria appear when disintegration is complete. Other bacteria were separated by selective methods. One of these, *Bact. croceum*, can grow in bouillon with 5 per cent. sodium carbonate, but neither it nor the others separated had any action upon experimental cement blocks. Since the disintegrated cement contained alkali soluble in water equal to 1·4 per cent. lime, the disintegration is probably purely physical.—Notes on *Vibrio denitrificans*, Sewerin, by R. Greig Smith. This is not a vibrion, but an organism morphologically similar to *Rhizobium leguminosarum*. In media containing potassium phosphate, branching and irregular forms are found in young cultures. It appears to be a budding rod, and the variety of forms of the organism is caused by the mother and daughter cells being contained in a branching capsule.

CAPE TOWN.

South African Philosophical Society, April 24.—Mr. L. Péringuey, president, in the chair.—Mr. Garwood Alston showed three photographs of stones standing erect about six miles south of Port Nolloth, near which Mr. R. Colson found certain kitchen-middens, from which a skull and several native pots and grinding stones were obtained. The stones form enclosures of four feet by two, running north and south. Two of the enclosures were dug into, but yielded nothing. The underlying indurated sand seemed to be quite undisturbed. Mr. Alston emphasised the absence of evidence as to the meaning of the enclosures, and said that the small size was against the view that old burial places are indicated.—Prof. J. T. Morrison communicated a paper on some pressure and temperature results for the Great Plateau of South Africa, by Mr. J. R. Sutton. The author discusses the annual run of daily maximum and minimum temperatures, and of daily barometric pressures at Kimberley and Durban, as deduced from observations made during the ten years 1888–97, the pressures at Kimberley being, however, available only for 1890–97. The object was to discover the outstanding features of plateau meteorology. The results suggest to the author that "we might adopt the working theory (not forgetting how easy it is to theorise when facts are few), which, however, is rather a geometrical conception than a mechanical possibility, that there is a certain temperature factor—if we may so call it—travelling round the earth from west to east, while a pressure factor is going the opposite way."

DIARY OF SOCIETIES.

THURSDAY, JUNE 6.

ROYAL SOCIETY, at 4.—Election of Fellows.——At 4.30.—On the Electric Response of Inorganic Substances, Preliminary Notice: Prof. J. C. Bose.—On Skin-Currents. Part I. The Frog's Skin: Dr. Waller, F.R.S.—Vibrations of Rifle Barrels: A. Mallock.—The Measurement of Magnetic Hysteresis: G. F. C. Searle and T. G. Bedford.—A Conjugating Yeast: B. T. P. Barker.——Papers to be read *in title only*: Thermal Adjustment and Respiratory Exchange in Monotremes and Marsupials: a Study in the Development of Homo-thermism: Prof. C. J. Martin.—On the Elastic Equilibrium of Circular Cylinders under Certain Practical Systems of Load: L. N. G. Filon.—The Measurement of Ionic Velocities in Aqueous Solution, and the Existence of Complex Ions: B. D. Steele.

ROYAL INSTITUTION, at 3.—The Chemistry of Carbon: Prof. J. Dewar, F.R.S.

LINNEAN SOCIETY, at 8.—On the Necessity for a Provisional Nomenclature for those Forms of Life which cannot be at once arranged in a Natural System (Adjourned Discussion): H. M. Bernard.

CHEMICAL SOCIETY, at 8.—A Laboratory Method for the Preparation of Ethylene: G. S. Newth.—Oroxylin: W. A. H. Naylor and C. S. Dyer.—Some Relations between Physical Constants and Constitution in Benzenoid Amines, II.: P. Gordon and L. Limpach.—The Constitution of the Acids obtained from α-Dibromocamphor: A. Lapworth and W. H. Lenton.—The Decomposition of Chlorates. IV. The Supposed Mechanical Facilitation of the Decomposition of Potassium Chlorate: W. H. Sodeau.—Condensation of Phenols with Esters of the Acetylene Series. V. Homologues of Benzo-γ-pyrone: S. Ruhemann.—On the Action of Sodium Methoxide and its Homologues on Benzophenone Chloride and Benzal Chloride: J. E. Mackenzie.—Preliminary Note on Hydrides of Boron: W. Ramsay and H. S. Hatfield.—Gum Tragacanth: C. O'Sullivan.

RÖNTGEN SOCIETY, at 8.30.—X-Ray Diagnosis of Aneurism: Dr. Hugh Walsham.

FRIDAY, JUNE 7.

ROYAL INSTITUTION, at 9.—Mimetic Insects: Prof. Raphael Meldola, F.R.S.

GEOLOGISTS' ASSOCIATION, at 8.—The Geysers of the Yellowstone: John Parkinson.

SATURDAY, JUNE 8.

ROYAL INSTITUTION, at 3.—The Biological Characters of Epiphytic Plants: Prof. J. B. Farmer, F.R.S.

MONDAY, JUNE 10.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Travels in Search of Waves in 1900: Vaughan Cornish.

VICTORIA INSTITUTE, at 4.30.—Annual Meeting.—Address by Sir Robert Ball, F.R.S.

TUESDAY, JUNE 11.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Notes from Five Years' Work with X-Rays: W. Webster.

THURSDAY, JUNE 13.

ROYAL SOCIETY, at 4.30.—Bakerian Lecture: Prof. James Dewar, F.R.S.—The Nadir of Temperature and Allied Problems. (1) Physical Properties of Liquid and Solid Hydrogen: (2) Separation of Free Hydrogen and other Gases from Air; (3) Electric Resistance Thermometry at the Boiling Point of Hydrogen; (4) Experiments on the Liquefaction of Helium at the Melting Point of Hydrogen; (5) Pyro-Electricity, Phosphorescence, &c.

MATHEMATICAL SOCIETY, at 5.30.—Remarks on the Quartic Curve $2\alpha^3\beta + m\beta^3\gamma + n\gamma^3\alpha = 0$: A. B. Basset, F.R.S.—The Theory of Cauchy's Principal Values, II.: G. H. Hardy.—The Rational Solutions of the Equation $u^3 + v^3 + w^3 + p^3 = 0$: Prof. Steggall.

CONTENTS.

THURSDAY, JUNE 13, 1901.

HUXLEY.

Life and Letters of Thomas Henry Huxley, F.R.S. By Leonard Huxley. Vol. I., pp. viii + 503; Vol. II., pp. vi + 504. (London: Macmillan and Co., Ltd., 1900.) 30*s*. net.

THE real life of Huxley has still to be written. What is wanted is a critical study of the development of his striking personality and an estimate of the work of his life and the effect it has produced. I have nothing but praise for the two bulky volumes of the "Life and Letters," in which a filial duty has been accomplished with taste and judgment. But though they supply invaluable material they do not attempt to bring the facts of either career or performance to a clear focus.

Such a study in competent hands would be a fascinating undertaking. It would not merely give a picture of a very remarkable man, but would give also a chapter in the history of English science of supreme importance. I make no pretension to ability for the task myself, even if the columns of this Journal could afford the space. But I shall hazard the attempt to indicate the essential points which I should like to see more amply treated. I have gathered the material from a pretty close study of the "Life and Letters," and I have added the references of volume and page to quotations, which are not always easy to find, for any one who cares to verify them.

Nothing in tracing an eventful career is so attractive as speculation on the "might-have-been." It is probable, however, that within narrow limits "circumstance" counts for little beyond giving a dramatic touch to the story. But it played its part again and again in Huxley's life for what it was worth.

His family traces back to the north-west of England, where a certain fibrousness of character is commoner than in the south. His father was a master in Dr. Nicholson's school at Ealing, where Huxley was born in 1825. He describes himself as "a thread-paper of a boy" (ii. 35) with "a wild-cat element in me" (i. 5). For education in the ordinary sense:—

"I had two years of a pandemonium of a school (between 8 and 10), and after that neither help nor sympathy in any intellectual direction till I reached manhood" (ii. 145).

The school came to grief and Huxley's father moved to Coventry. Huxley was left to his own devices. What they were is almost incredible; but then he has told us that "*a priori* reasonings are mostly bosh" (ii. 212). At twelve he was sitting up in bed before dawn to read Hutton's "Geology" (i. 6). His great desire was to be a mechanical engineer; it ended in his devotion to "the mechanical engineering of living machines" (i. 7). His curiosity in this direction was nearly fatal; a *post mortem* he was taken to between thirteen and fourteen was followed by an illness which seems to have been the starting point of the ill-health which pursued him all through life. At fifteen he devoured Sir William Hamilton's "Logic." Twenty years later he says:—"From that time to this ontological speculation has been a folly with me" (i. 218). At seventeen he came under the influence of Carlyle. Nearly fifty years later he wrote:—

"There is nothing of permanent value (putting aside a few human affections), nothing that satisfies quiet reflection—except the sense of having worked according to one's capacity and light, to make things clear and get rid of cant and shams of all sorts. This was the lesson I learnt from Carlyle's books when I was a boy, and it has stuck by me all my life" (ii. 268).

At the same age he began his regular medical studies at Charing Cross Hospital with his brother, to whom Newman (afterwards Cardinal), who had been educated at the Ealing school (i. 19), gave a testimonial. He attended Lindley's lectures at the Chelsea Botanic Garden and won one of the medals of the Apothecaries Society. At the Medical School he studied under Wharton Jones, a physiologist who never seems to have attained the reputation he deserved. Perhaps he got mixed up with "the other fellow," who, Huxley thought, had "mistaken his vocation" (i. 94), an opinion in which, from personal experience, I can quite agree. Of Wharton Jones, Huxley says:—

"I do not know that I ever felt so much respect for a teacher before or since" (i. 21).

At twenty he went up for his First M.B. examination at the University of London, winning the gold medal for anatomy and physiology. Ransom, of Nottingham, won the Exhibition. Here circumstance came in.

"If Ransom had not overworked himself . . . . I should have obtained the Exhibition . . . . and should have forsaken science for practice" (ii. 133).

Would he?

Something had to be done to get a livelihood, and at the suggestion of a fellow student, now Sir Joseph Fayrer, he applied for an appointment in the Navy. Circumstance again, he came under Sir John Richardson, himself no mean naturalist, and through his influence was attached to the *Rattlesnake*. One of the oddest things about Huxley's career is the fact that almost every one he had to do with turned out sooner or later to be somebody notable. Through his Captain, Owen Stanley, "a thorough scientific enthusiast" (i. 25), he was introduced to Owen, Gray and Forbes, the first and last of whom had a good deal to say to his future career. The voyage of the *Rattlesnake* occupied four years. Huxley was twenty-five on his return. Few scientific men ever used their opportunities with keener sagacity. He spent no time in mere collecting. But, with an instinct which appears to me altogether extraordinary in one who was little more than a youth fresh from a medical school, he seized upon everything that was important and with regard to which new ground was to be broken; and, characteristically, he steadily kept their physiological interest to the front. The rest may be passed over rapidly; he had, in a scientific sense, his reward. His paper on the structure of the Medusæ had been published during his absence in the *Philosophical Transactions*. In this paper he laid down the fundamental character of the "ectoderm and endoderm." As Allman justly remarks, "this discovery stands at the very basis of a philosophic zoology" (i. 40). It is not too much to say that it is the foundation of modern zoological theory, and had Huxley never done anything else he would still have retained a classical place in its history.

At twenty-six he was elected a Fellow of the Royal Society. At twenty-seven he not merely received the Royal medal, but was placed on the Council. Certainly, half a century ago, our venerable Society showed no want of alacrity in recognising rising merit. And if any one wants to suggest that it has become less active in that respect he may be reminded that it was equally prompt in the case of Hertz.

It is certainly a notable circumstance that three men who were contemporaries and ultimately close friends, Darwin, Hooker and Huxley, each began his scientific career on board one of Her Majesty's ships. The consequence in each case was momentous to science: Darwin gave us the "Origin," Hooker a rational theory of geographical distribution, Huxley a reformed zoology. The odd thing is that while the two former returned confirmed naturalists the latter came back as impenitent as ever, and never was of a better mind till quite the end of his life.

At the age, then, of twenty-seven Huxley had placed himself with absolutely no aid in the very front rank of English scientific men. "What makes," he says, "the bigwigs so marvellously zealous on my behalf I know not. I have sought none of them and flattered none of them" (i. 78). Yet he did not emerge from the struggle altogether unscathed. Writing to Kingsley some eight years later he for once allows the cry of the wounded heart to escape him:—

"Kicked into the world, a boy without guide or training, or with worse than none, I confess to my shame that few men have drank deeper of all kinds of sin than I have" (i. 220).

Frankly, I do not believe a word of it. My experience of life does not lead me to think that any one who begins with a rank crop of weeds is very likely to ever reap a more substantial harvest. The plain fact is that the mood of confession is a perilous one, and from St. Augustine onwards most men who have yielded to it have found a sort of painful satisfaction in painting their past in the blackest colours. But I am entirely unable to find any point in Huxley's youth at which I can fix that outburst of the natural man. In a rather serious conversation I once had with him he spoke of a period in his life when he *might* have taken to evil courses; but he did not give me the smallest reason to suppose that in the retrospect he saw more than the existence of a possible *crevasse* in his path into which he might have fallen.

If Huxley's scientific reputation was established, his material position was still unassured. "Nothing," he says, "but what is absolutely practical will go down in England. A man of science may earn great distinction, but not bread" (i. 66). The struggle, however, in his case, if sharp, was less prolonged than it has been in the case of many other men. Owen got him his first temporary appointment (i. 95). Edward Forbes, "a regular brick"—an opinion I never heard any one gainsay—backed him "through thick and thin" (i. 107). He refrained, therefore, happily, from abandoning "all his special pursuits and take up chemistry, for practical purposes" (i. 86). He had tried to get "crystallised carbon" at fifteen (i. 10)!

Huxley was now thirty, and at last happily married. He might have succeeded Forbes in the Edinburgh chair, but "preferred to live in London on a bare sufficiency" (i. 120). He settled down at the School of Mines; his ship had come into port; what was the cargo he brought with him? As a boy he conceived a profound distrust of metaphysical speculation; at fifteen he writes in his note-book, hammered out from "Novalis," "Philosophy bakes no bread" (i. 9); that he stuck to to the end. From Carlyle he learnt his empiricism, a determination to see things as they are. From Wharton Jones he acquired an exact method, and from the *Rattlesnake* voyage confidence in his own powers of observation and courage to criticise the word of others. And here I must interpose the remark that it is difficult to estimate the services which biological science in this country owes to our medical schools. Up to the present time without them it would possibly not have existed amongst us at all. Huxley later on was more willing than I am to kick away the ladder:—

"Our side has been too apt to look upon medical schools as feeders for science. They have been so, but to their detriment as medical schools. And now that so many opportunities for purely scientific training are afforded, there is no reason that they should remain so" (ii. 310).

For my own part, owing much to medical training, I entirely dissent. The foundation of medical studies on a scientific basis, far from being detrimental, has in my opinion been of incalculable benefit to them. If Huxley really contemplated a division between medicine and science it was the worst cause he ever advocated.

Huxley's official duties, much against the grain, brought him face to face with palæontological problems. This not merely led to some of his most brilliant work, but put a weapon in his hand which he used afterwards with irresistible effect.

Half a century ago Owen was the dominant, and I think it must be admitted an evil, influence in the English biological world. He was saturated with the "naturphilosophie" and the teaching of Oken. Huxley was bound to come into collision with this. The Croonian Lecture in 1858, "On the theory of the vertebrate skull," demolished Oken's theory, and with it "fell the superstructure raised by its chief supporter, Owen, 'archetype' and all" (i. 141). Owen had already felt that his throne was tottering and, having borrowed the lecture-room in Jermyn Street for a course of lectures, boldly assumed, without the smallest warrant, the title of "Professor of Palæontology at the School of Mines" (i. 142). For this and many subsequent proceedings of a like nature the only plausible explanation that I can see is lunacy.

Here again Huxley laid one of the foundation stones of modern biological science. In his paper on the Medusæ he supplied the key which has unlocked the secrets of embryology; his Croonian lecture, followed by the work of Gegenbaur, has placed vertebrate morphology on a scientific basis.

This was his first conflict with scientific idealism, but it was a mere affair of outposts compared with the campaign that was to follow. He tells us :—

"I was not brought into serious contact with the 'species' question until after 1850. At that time I had long done with the Pentateuchal cosmogony . . . . from which it had cost me many a struggle to get free" (i. 167).

Later on he calls "the hypothesis of special creation . . . . a mere specious mark for our ignorance" (ii. 302). What was to be put in its place? Herbert Spencer, whose acquaintance he made in 1852, was unable to convert him to evolution (i. 168). He could not bring himself to acceptance of the theory—owing, no doubt, to his rooted dislike to *a priori* reasoning—without a mechanical conception of its mode of operation. Like Darwin, he derived no comfort from either Lamarck or the "Vestiges" (i. 168). For the former, nevertheless, he always entertained the most profound respect, and thought he would run Darwin "hard both in genius and fertility" (ii. 39). His review of the latter was the only one he ever had "qualms of conscience about on the grounds of needless savagery" (i. 168).

His attitude to evolution continued to remain altogether sceptical and stand-off. In his first interview with Darwin, which seems to have been about 1852, he expressed his belief "in the sharpness of the lines of demarcation between natural groups," and was received with a "humourous smile" (i. 169). Hooker, on the other hand, he thought "*capable de tout* in the way of advocating evolution" (i. 170); but then Hooker was in the secret.

Before continuing the story I think it will be helpful to state in simple terms the problem that Darwin attempted to solve, and to which he got his first clue in the Galapagos. Take a number of organisms at random and proceed to sort them according to their resemblances. When this has been done it will be found that they have fallen into groups larger or smaller, as the case may be. The members of the groups will closely agree in all essential particulars; they are *individuals*. Yet no two are exactly alike; this is *variation*. Yet within the group there will be nothing to oppose the view that each may pass into the other; the variation is *continuous*. This will not be the case in comparing groups themselves; the variation is more marked and *discontinuous*. The discontinuity can be expressed in technical terms, and these give us an abstract definition of the *species* or the distinctive marks common to the individuals forming the group. Treating species in the same way we arrive at a series of discontinuous groups of a higher order; these are *genera*. Continuing the process we obtain *families*. Proceeding onwards in the scale we find ourselves face to face with two, perhaps the most difficult of all to define—the Vegetable and Animal kingdoms.

Now Darwin, of course, saw with every one else that if the mode of origin of groups of the first order could be explained, all the rest followed. What was wanted was the discovery of some intelligible agency which could effect the passage of one organic form to another. As Huxley put it :—

"That which we were looking for, and could not find, was a hypothesis respecting the origin of known organic forms which assumed the operation of no causes but such as could be proved to be actually at work" (i. 170).

Darwin assumed continuous variation as an empirical fact and "natural selection" as the agency which had directed the course of organic evolution. This was a generalised form of the "artificial selection" which the cultivator and the breeder use every day in moulding organic nature pretty much as they will. As Huxley says :—

"My reflection when I first made myself master of the central idea of the "Origin" was, 'How extremely stupid not to have thought of that'" (i. 170).

Huxley's attitude to Darwinism deserves careful study. Some have thought that in his last public appearance at Oxford in 1894 he hinted his willingness to make a present of Darwin's theory to Lord Salisbury, as organic evolution could be established without it. And no doubt that is a view which can be maintained. Lord Salisbury had ridiculed the idea of the advantageous male in pursuit of the advantageous mate. This only showed that he could have studied Darwin to very little purpose. I am not one of those who think that the discontinuous "sport," advantageous or not, has played much part in evolution. But in any case its appropriate pairing is not essential, as it is now known that sports are frequently prepotent and their influence not easily swamped. The unmatched advantageous male is not so easily dismissed as Lord Salisbury seemed to think.

Huxley found in Darwin what he had failed to find in Lamarck, an intelligible hypothesis good enough as a working basis. But with the transparent candour which was characteristic of him he never to the end of his life concealed the fact that he thought it wanting in rigorous proof.

Now Darwin was a naturalist, and the "Origin" is emphatically the production of a naturalist. Huxley has repeatedly told us, what is perfectly true, that he was not one himself. "His love of nature had never run to collecting either plants or animals" (ii. 443). For him as for others Lyell "was the chief agent in smoothing the road to Darwin" (i. 168), for evolution is implied in uniformitarianism. Huxley was an anatomist, and the distinctions of the higher groups with which he chiefly occupied himself are anatomical. The discontinuity of those groups no longer troubled him now that he knew what lay behind Darwin's "humourous smile." But with "species" or primary groups he still found difficulties which I think he would not have found if he had had a naturalist's experience. At Edinburgh :—

"In common fairness he warned his audience of the one missing link in the chain of evidence—the fact that selective breeding has not yet produced species sterile to one another" (i. 193).

He states the point more precisely in a letter to Kingsley :—

"He (Darwin) has shown that selective breeding is a *vera causa* for morphological species; he has not yet shown that it is a *vera causa* for physiological species" (i. 239).

Now it seems to me that, to use one of his own favourite expressions, this is a shadow of the mind's own throwing. The species which Darwin undertook to account for are morphological. No other category conveys any meaning. There is a physiological difference between the sweet and bitter almond, because one is harmless and the other will kill; but it is unaccompanied by the smallest morphological distinction. Nägeli pointed out the importance of recognising this in bacteriology. What Huxley really meant by physiological species are species which are mutually sterile, and in this both he and Romanes seem to me to have rather begged the question.

Darwin, who was more aware of the weak points of his theory than any of his critics, took immense pains to show that sterility does not run parallel with taxonomic order. It is well known that it is *not* a criterion of species, as Huxley seemed to think—it does not seem to be even a criterion of genera. I can only suppose that some hint of Huxley's furnished the foundation of Romanes's heroic attempt to establish "physiological selection." If so, Huxley seems to have been little impressed with the result:—

"It (the 'Origin') is one of the hardest books to understand thoroughly that I know of, and I suppose that is the reason that even people like Romanes get so hopelessly wrong" (ii. 192).

But then Romanes was not a naturalist either.

Another difficulty was the principle that "*Natura non facit saltum*" (i. 176), and I think from the same cause. Bateson, of course, receives a benediction:—

"I always took the same view, much to Mr. Darwin's disgust" (ii. 372).

That "considerable 'saltus'" may occur is not improbable; but there can be little doubt that a species passes from one configuration to another, as Darwin supposed, by minute changes; and, as he has himself pointed out, we are not justified in assuming that the rate of variation has always been uniform.

Huxley, however, felt that he had at last a secure grip of evolution, and was soon on the war path; he warns Darwin:—

"I will stop at no point as long as clear reasoning will carry me further" (i. 172).

Nor did he. The history of "the great 'Sammy' fight" has often been told. It is interesting to know that it was Chambers, the author of the "Vestiges," who was responsible for it (i. 188). Its importance has been somewhat exaggerated. Evolution has made its way by a process of slow permeation. It has done so because, in the words of Helmholtz, it contains "an essentially new creative thought" (i. 364). But it was a brilliant dialectic victory for Huxley, and Oxford loves dialectic: "The black coats . . . offered their congratulations" (i. 189). "The Bishop . . . bore no malice, but was always courtesy itself" (i. 188). Huxley was, however, less forgiving, and put him in his pet little Inferno (ii. 341). Personally I entertain more than a sneaking admiration for him. He "cleaned up" the diocese of Oxford with a vigour worthy of Huxley himself.

One incident in the discussion is of some theoretical interest. The permanence or, as I prefer to say, stability of species seem to have been adduced as an argument against Darwin's theory. Lord Avebury:—

"instanced some wheat which was said to have come off an Egyptian mummy, and was sent to him to prove that wheat had not changed since the time of the Pharaohs, but which proved to be made of French chocolate" (i. 187).

But we have absolute evidence from tombs that Egyptian plants have not appreciably changed for 4000 years. And it is now known that the fact, instead of being an argument against, is rather one for the Darwinian theory.

Owen made a last desperate attempt to save the situation by asserting for man, on anatomical grounds, a completely isolated position in the animal kingdom. Huxley, in 1862, "showed that the differences between man and the higher apes were no greater than those between the higher and the lower apes" (i. 192). The case for the evolution theory was now complete.

Carlyle did not forgive the publication of "Man's Place in Nature," though it only carried the veracity of "Sartor Resartus" a step further. However, master and disciple both received together an honorary degree at Edinburgh, and I think there must have actually been some sort of reconciliation. For I have a distinct remembrance of hearing, I think from Huxley himself, that Carlyle expressed to him unbounded admiration for "Administrative Nihilism," coupling it with a by no means flattering estimate of another eminent philosopher.

Here I must leave Huxley's scientific work. He was now only thirty-seven. He found zoology in this country enchained in fantastic metaphysical conceptions; he extricated it almost single-handed. Writing to Leuckart in 1859 he says:

"Ten years ago I do not believe there were half-a-dozen of my countrymen who had the slightest comprehension of morphology. . . . I have done my best, both by precept and practice, to inaugurate better methods. . . . I confidently hope that a new epoch for zoology is dawning amongst us" (i. 163).

The hope has been amply realised. And if a quickening spirit has been breathed into every branch of biological teaching in this country, it was Huxley it came from. It is much to be wished that some one would record some recollections of the memorable courses of instruction at South Kensington which Huxley commenced in 1871, in which teachers and taught were alike inspired by an enthusiasm the tension of which almost reached breaking point, and in Huxley's own case, in fact, speedily did so.

Notwithstanding ill health his mental activity, constantly stimulated by a certain innate combativeness, kept him to the end immersed in public work of the most varied description and in the controversy that he loved. "Under the circumstances of the time," he says, "warfare has been my business and duty" (ii. 213). All this it is needless for me to touch upon. But no picture of Huxley would be complete which left out of sight the speculations which more and more absorbed him as his life drew to a close. In this Journal these can be only treated from a purely scientific point of view.

It is necessary to remember that Huxley's grasp of the principle of organic evolution was only arrived at by the process of reasoned and by no means hasty conviction. He satisfied himself that man could not be excluded from it. He was naturally therefore drawn to discuss human phenomena in relation to evolution.

The first was the problem of ethics. He summed up his conclusions in the Romanes lecture delivered at Oxford in 1893. This was his second speech delivered there; the first was in the "great Sammy fight," thirty-three years before. He might well say that "Oxford always represents English opinion in all its extremes" (ii. 441). He nearly succeeded in producing as much hubbub as on the first occasion. It is amusing, if not very edifying, to read the anxious preliminary negotiations. Huxley wrote, "Of course I will keep clear of theology" (ii. 350), and Romanes naturally writes back "in great alarm" (ii. 354). The pith of the whole thing was, "the cosmic order is not a moral order."

Morals are part of the cosmic order, but not identical with it. Seriously regarded, this is a very simple statement of pure fact, which is indeed the basis of one of Dr. Watts's most familiar "Sacred Songs," the orthodoxy of which no one has ever impeached. The order of nature is self-regarding, and, as that familiar writer implies, society "would be dissolved by a return to the state of simple warfare among individuals" (ii. 352). The contrary view, embodied in the phrase "ethics of evolution," Huxley traces to the ambiguity of the word "fittest." That "which survives in the struggle for existence may be, and often is, the ethically worst" (ii. 303).

"The actions we call sinful are part and parcel of the struggle for existence . . . and have become sins because man alone seeks a higher life in voluntary association" (ii. 282).

So far this is a utilitarian theory of morals, and, as far as it goes, accounts for the phenomena. But, as Huxley saw, it leaves unexplained the fact that probably every ethical system aims at a higher standard than is ordinarily reached or is perhaps even necessary in practice. This apparently he would explain by "an innate sense of moral beauty and ugliness (how originated need not be discussed)" (ii. 305). I confess I am sorry for that parenthesis. But the principle itself is comparable to Matthew Arnold's "Something not ourselves which makes for righteousness." At any rate, short work is to made of those who do not possess it.

"Some are moral cripples and idiots, and can be kept straight not even by punishment. For these people there is nothing but shutting up or extirpation" (ii. 306).

I hope it is not irreverent to say that "Injuns is pisin" seems to be a natural corollary. Huxley meant to look up Nietzsche (ii. 360), but probably never did. Had he done so the result would have been edifying.

A critical study of Huxley's theological views, especially in the light afforded by the "Life and Letters," would be extremely interesting. This is not the place to attempt anything of the sort. But some brief account is necessary. The starting point is to be found in a letter to Kingsley:—

"'Sartor Resartus' led me to know that a deep sense of religion was compatible with the entire absence of theology" (i. 220).

Now this suggests two remarks which are both justified, I think, by my own personal knowledge. In the first place I am firmly persuaded that he, if any one, was a deeply religious man. I am equally persuaded that he had a perfect passion for technical theology. He often thought himself, at least so he told me, that he might have been a successful lawyer. I do not doubt it. But the cerebral equipment which might have found employment in that direction got turned on to theology. This, I think, throws light on his shortcomings in this field. Dogma may be treated, and I think should be, in a scientific spirit; Huxley too often indicted it as if he were in a police court. There is no doubt that he adopted this attitude deliberately.

"My object has been to stir up my countrymen to think about these things; and the only use of controversy is that it appeals to their love of fighting and secures their attention" (ii. 291).

"I must," he says, "have a strong vein of Puritan blood in me somewhere" (ii. 91), and I think it cannot be doubted that he was right. His point of view was that of an extreme nonconformist. I need not say that this implies no disrespect, for nonconformity has been one of the roots of the English character.

In one aspect the religious sentiment is a response to the craving for a supernatural sanction to rules of conduct. Its varied but practically universal manifestation amongst mankind has got to be accounted for by evolution just as much as the possession of a vertebral column. It is not practically helpful to dismiss it as irrational.

Huxley, like others of a Puritan temperament, had more liking for the Old Testament than the New: "the only religion that appeals to me is prophetic Judaism" (ii. 339). But Calvinism, I think, contained much with which he most nearly sympathised. "Science," he wrote to Kingsley, "seems to me to teach, in the highest and strongest manner, the great truth which is embodied in the Christian conception of entire surrender to the will of God" (i. 219). "I have the firmest belief," he continues, "that the Divine Government . . . . is wholly just." There is a very interesting passage, too long to quote (ii. 303), in which he points out that "the best theological teachers . . . . substantially recognise these realities of things, however strange the forms in which they clothe their conceptions." For my own part, I wish he had applied the principle which is implied here in some of his controversial essays. Writings thousands of years old would have been unintelligible if they had not been expressed not merely in the language but in terms of the ideas current at the time. The demonology of the first century was scarcely worth the powder and shot bestowed upon it. If it had cost Huxley himself "many a struggle to get free" from the Pentateuchal cosmogony (i. 167), he lived to see Canon Driver give up its "physical truth . . . . altogether" (ii. 218); the process of attrition of what is superfluous will go on.

Huxley, however, in his episcopophagous mood was a grievous disappointment to extremists when it came to practical business. It is difficult, I think, to exaggerate the importance of the work he did on the London School Board and at a terrible cost to his health. He expressed "his belief that true education was impossible without 'religion,' of which he declared that all that is unchangeable in it is constituted by the love of some ethical ideal to govern and guide conduct" (ii. 340), and he unhesitatingly adopted the words of Mr. Forster in 1870:—

"I have the fullest confidence that in the reading and explaining of the Bible what the children will be taught will be the great truths of Christian life and conduct, which all of us desire they should know" (ii. 344).

He fought, therefore, "for the retention of the Bible, to the great scandal of some of my Liberal friends," and "never had the slightest sympathy with those who, as the Germans say, would 'throw the child away along with the bath'" (ii. 9).

Years after he remained of the same mind:—

"I do believe that the human race is not yet, possibly may never be, in a position to dispense with it" (ii. 300).

Ethical and religious problems occupied so large a place towards the end of Huxley's life that it was impossible to leave them out of sight. But a sharp distinction is, I think, to be drawn between what he accomplished in this field and what he did for knowledge. The latter was eminently constructive: he reconstituted biological science in this country from the foundations upwards. The former was only critical and, as he did not deny, mainly negative. His defence was that his part had been to clear "the ground for the builders to come after him" (ii. 301). Meanwhile he had nothing but respect for those who honestly held opposite views. But he would have nothing to do with the "half-and-half school," with whom he had less sympathy than "with thorough-going orthodoxy" (i. 471). For Magee, Bishop of Peterborough, he had "a great liking and respect" (ii. 244). I wish I felt at liberty to amplify what is said (ii. 205) as to the admiration he conceived for Father Steffens.

Looking back on the whole story as I have attempted to tell it, I am struck with the character of inevitableness about Huxley's career. I do not call to mind any other in which a controlling purpose so definitely manifests itself. "My sole motive," he said in 1891, "is to get at the truth in all things. I do not care one straw about fame, present or posthumous" (ii. 281), and certainly, so far as it is given to any one to be successful, he obtained a large measure of success.

Much has been said of the odium and obloquy he encountered in the process. He was certainly supremely indifferent to both, and probably rather enjoyed them. But Englishmen will concede anything to honesty, and Huxley was transparently honest. And obloquy is perhaps not intolerable which is accompanied by the repeated offer of a professorship at Oxford, followed by that of the headship of a college, by the presidency of the Royal Society, and by admission to the Privy Council.

But it was not merely as a man of science and of affairs that Huxley achieved success. He was possessed of an extraordinary literary gift. "I have," he writes, "a great love and respect for my native tongue, and take great pains to use it properly" (ii. 291). It is much to be wished that scientific men generally would follow his example. He could always, says Sir Spencer Walpole, "put his finger on a wrong word, and he always instinctively chose the right one" (ii. 25). But this, like everything else that he ever did, was not accomplished without labour. It was from the literature of the eighteenth century that young Englishmen "would learn to know good English when they see or hear it" (ii. 285). In his own case it helped to make him, as Mr. Arthur Balfour said, a great master of English prose; perhaps even, as Sir Spencer Walpole thinks, "the greatest master of prose of his time" (ii. 25).

Nor less sedulously did he cultivate the art of oral exposition and of public speaking, or with less success. Lord Salisbury exclaimed, "What a beautiful speaker he is" (ii. 25). Apart from eloquence as it is ordinarily understood, or rhetorical effect, I myself have never heard any one who in method or manner could compare with him. It is quite consistent with this that he should say, "I funk horribly, though I never get the least credit for it" (i. 311). Before one of his greatest performances he asked me to take his hand: it was stone-cold. "It is always like that," he said. Yet he held an enormous audience enchained while he unfolded, using no notes, but with faultless choice of words, an intricate and technical argument.

Nor was he less captivating in conversation. He rises to my mind's eye, drawing down his mouth when he was serious, as if to give momentum to the propulsion of the thought. In a moment, as some humorous aspect of the matter struck him, it would relax into a smile, and then, if one tried too audaciously to attack his arguments, his head would go back with a leonine sweep, as much as to say, "young man, be careful." But it was what Mr. Skelton admirably calls "the Shakespearian gaiety of touch" (ii. 16) that made converse with him so unforgettable. Darwin had something of it, but attuned to a gentler key. With Huxley it was irrepressible. "I suppose," he says, "I shall chaff some one on my death-bed" (ii. 76).

But, in truth, through these two volumes there runs a tragi-comedy, often moving to mirth and not seldom to tears, and sometimes almost Meredithian in intensity. The demon of dyspepsia broods over the drama, as it unfolds, like fate. The wonder is that a man who fought such a life-long battle with ill-health could oppose such a courageous and uncomplaining front to the outside world. He carried the fox gnawing at his vitals with a Spartan fortitude.

And to ill-health there was added, for no small portion of his life, the no less uncomplaining struggle with poverty. To keep his brother's widow he was even compelled to part with his Royal medal (i. 248). When he retired from the public service it was the desire of the Education Department that he should do so on a full pension. This the Treasury were unable to grant. But it is to be counted to the credit of a Tory Government that the amount was eventually made up from the Civil List.

A few words and I have done. In these volumes the reader has the privilege of being brought into as frank an intimacy with Huxley as was enjoyed by even his closest friends. I am wholly mistaken if there does not emerge from their perusal a personality of singular fascination behind which lay an intellectual and moral force, second perhaps to none in its influence on his countrymen during the latter half of the century which has closed.

As Lord Hobhouse has said, "he fought the battle of intellectual freedom" (ii. 407), and his success was due to the integrity of purpose and dauntless courage which never failed him. Sir Spencer Walpole says justly,

"Of all the men I have ever known, his ideas and his standard were—on the whole—the highest" (ii. 27).

He proceeds—

"He recognised the fact that his religious views imposed on him the duty of living the most upright of lives."

A very unfair use has, I think, been made of this opinion, which I am persuaded is based on a profound misconception. However derived, it is in an innate sense of moral beauty that I prefer to find the true secret of Huxley's life. W. T. THISELTON-DYER.

TERRESTRIAL MAGNETISM AND ATMOSPHERIC ELECTRICITY.

The Norwegian North Polar Expedition, 1893-96. *Scientific Results.* Edited by Fridtjof Nansen. Vol. ii. (London: Longmans, Green and Co., 1901.)

Report on Observations in Terrestrial Magnetism and Atmospheric Electricity made at the Central Meteorological Observatory of Japan for the Year 1897. Pp. 60. (Tokio: Central Meteorological Observatory.)

THE first of the above volumes consists of three memoirs, numbered VI., VII. and VIII., written respectively by Prof. H. Geelmuyden, Mr. Aksel S. Steen and Prof. O. E. Schiøtz. In a brief preface Dr. Nansen states that the great majority of the observations dealt with were made by Captain Sigurd Scott-Hansen.

VI. *Astronomical Observations.*—In a preface, pp. vii. to lx., Prof. Geelmuyden describes the astronomical instruments and the circumstances of their use. His principal object is to determine the drift of the *Fram* and the track of Nansen and Johansen after leaving the ship. The results are embodied in two large scale charts (in a pocket at the end of the volume). A second object is to determine the azimuth in connection with the observations of magnetic declination.

The latitude and local time were found by altitude observations, the sun alone being available during part of the year. For the determination of longitude, and of the chronometer rates, a variety of data were accumulated. There were observations during two eclipses, a few lunar distances and a number of observations of eclipses of Jupiter's satellites. In connection with these last data there is an enumeration of corresponding observations at various observatories, and a discussion of the theory and of various sources of uncertainty. The differences between the chronometers in use from 1893 to 1896 are recorded and discussed. The difficulties met with in reducing the astronomical observations are considerable. Most referred to a station in motion, while many were taken at extremely low temperatures, under conditions when ordinary astronomical formulæ for refraction, &c., are open to question. The differences between the chronometers are not always easy to explain, and the data as to their temperature corrections are somewhat uncertain. As to the data obtained by Nansen and Johansen in their journey, in Prof. Geelmuyden's words,

"the observations during this expedition, where the principal work of the travellers was very often a struggle for life, and where the instruments had to be handled in temperatures down to $-40°$ C., with no other source of heat than the observer's own body, could not attain any high degree of accuracy" (p. lvii.).

The fact that the observations were made at all is the strongest possible evidence that scientific zeal is compatible with the possession of remarkable physical courage and resolution.

After Geelmuyden's preface follow tables, pp. 1-136, giving full details of all the astronomical observations, with a few explanatory notes.

VII. *Terrestrial Magnetism.*—In his introduction, pp. 1-9, Steen describes the instruments. Acknowledgment is made of the assistance rendered by Dr. Neumayer, of Hamburg, who selected the apparatus and had some of it made under his own eye. The great majority of the observations were taken on the ice, inside a tent or a house of snow or ice. "As a defence against bears . . . a weapon was always at hand, generally a revolver." The position of this useful but embarrassing auxiliary and its influence, or absence of influence, on the magnets is a frequent item in the observational records. The different magnetic elements are discussed separately. The declination observations occupy pp. 10-61. The majority were taken with a "Neumayer Declinatorium," of which the principal feature is that its magnet consists of "two laminæ, between which the mirror was fixed"; the magnet rested on a pivot, but could be inverted so as to determine or eliminate the collimation error. Declination results are also deduced from the deflection experiments, intended primarily for the determination of the horizontal force. There were in all about 130 days on which declinations were obtained. The *changes* observed during each of these days are shown graphically, occupying seventeen plates. The observations seldom extended over more than two or three hours on any one day, and in no case was there a continuous day's record. On November 24, 1894, in the course of fifteen minutes, the declination changed fully 26°. On no other occasion did the observed range exceed a quarter of this; but changes of 2° or 3° in the course of an hour or two were not uncommon.

The discussion of the horizontal force observations occupies pp. 62-126, the results being summarised on pp. 119-126. The apparatus was by Zschau. Observations of vibration and deflection were made much in the usual way. The moments of inertia of the two magnets used had been determined, but only approximately, and instead of employing the values so calculated use is made for each magnet of a "constant," involving the moment of inertia, which was determined by observations made at Hamburg and Wilhelmshaven. In some instances the horizontal force is deduced from a deflection experiment alone, by means of a second "constant" involving the magnetic moment of the deflecting magnet. The times of vibration were taken without a telescope, and no observations were made on the torsion of the silk suspension. Mr. Steen also experienced some trouble in connection with the temperature coefficients, which had not been determined at Arctic temperatures.

The inclination observations are discussed on pp. 127-165. The instrument used was a Fox circle, as modified by Neumayer, with two needles and deflectors. In all there were ninety-two observations of inclination. In treating them, Mr. Steen encountered difficulties. In general, the magnetic axis of a dip needle is inclined to the line of geometrical symmetry, the position of which is read, while the C.G. departs from the axis of rotation. The former source of index error is usually eliminated by reading the needle with its face alternately towards and away from the face of the circle; whilst the latter source of error is removed by reversing the needle's magnetisation in the middle of each experiment. The needles, however, of a Fox circle are never reversed, and the observer in the present case had always used the needles in an invariable position. Assuming constancy in the magnetisation, the error from the first source would remain constant, but that from the second source would vary with the inclination. The resulting error is represented by Mr. Steen through a formula involving three unknown constants, but he finds the data insufficient for determining these directly. Eventually, by having recourse to some results obtained with the deflectors of the Fox apparatus and to corresponding values obtained for the horizontal force, and making certain assumptions, he arrives at numerical results. Some doubt may, however, be felt as to the measure of success attending Mr. Steen's courageous efforts, and this is the more to be regretted because the index correction applied averages about 50′.

The total intensity is dealt with on pp. 166–180. A considerable number of observations had been made with the Fox apparatus; the data, however, for converting these to absolute measure were not, in Mr. Steen's opinion, satisfactory. Accordingly, he contents himself with a list of the observational results,

"partly for possible future utilisation, and partly, too, to show what might have been done with the instrument if the necessary determination of the constants had been forthcoming" (p. 168).

Mr. Steen finishes with two tables, the first, pp. 183–188, summarising the individual results for the magnetic elements, along with the corresponding *theoretical* results, which Dr. Ad. Schmidt had the kindness to calculate from his values of the Gaussian constants for the epoch 1885. The discrepancies, which in the case of both the horizontal force and the inclination seem always of one sign, are often considerable. This may be partly due to the secular change, for which no allowance could be made. The second table arranges the observational results in groups.

VIII. *Pendulum Observations.*—Prof. Schiøtz in his introduction describes the apparatus, which consisted of a von Sterneck's outfit with two half-second pendulums. The periods were observed at Vienna, also at Christiania before and after the expedition, and Schiøtz concludes that practically no change had occurred. During the expedition one observation was made on shore near the Kara Sea, three on the ice, and seven inside the *Fram* when frozen in. Particulars of each experiment are given in full. The geographical coordinates of the stations and the corresponding times of swing are summarised on p. 55. To deduce absolute values for *g*, Schiøtz utilises the times of swing observed at Vienna and Christiania, together with the absolute values found for gravity at these places by von Oppolzer and himself. The values thus deduced for gravity at the polar stations are compared on p. 60 with the theoretical values given by Helmert's formula for *g*. Of the ten experiments taken on board ship or on the ice, five give values above and five values below the theoretical. The mean departure from the theoretical values, taken irrespective of sign, amounts only to three parts in 100,000; on the average the observed value exceeds the theoretical by one part per 100,000. Schiøtz believes, however, that the irregular movements due to ice motion must have slightly increased the observed values of *g*. His conclusion on p. 63 is as follows:

"The observations show that gravity may be regarded as normal over the polar basin; and as it is not probable that this is a peculiarity of the Polar Sea, we are led to the assumption that gravity is normal all over the great oceans. The increased attraction observed on oceanic islands must, therefore, only be due to the local attraction of the heaped up masses . . . that form the islands."

Prof. Schiøtz seems here rather a long way from his base. He devotes pp. 63–86 to drawing "some conclusions respecting the constitution of the earth's crust." A supplement, pp. 87–90, advances arguments which, in Schiøtz's opinion, justify the belief that the influence due to the lack of absolute rigidity in the supports on the pendulums' periods was the same throughout the voyage as at Christiania.

The writers of the three memoirs have clearly acted on the view that the circumstances of Nansen's polar journey were so unique as to justify an unusual amount of detail in recording the observations, and they have spared themselves no trouble in their anxiety to utilise the data to the very utmost. A critic may perhaps, however, be pardoned the doubt whether greater compression of details and greater reserve in theoretical deductions might not have led to a work of fully greater utility. Be this as it may, the volume is to be welcomed as exceedingly opportune in view of the approaching Antarctic expeditions. Those responsible for the exercise of foresight in connection with the apparatus, or the observational programmes of these expeditions, would be well advised in giving its contents their careful consideration.

According to the preface of the second work mentioned at the head of this notice, the Central Meteorological Observatory of Japan, at Tokio, was established in 1890, and "was rebuilt in July, 1897." (?) It possesses two underground magnetic rooms, one for photographically recording, the other for eye-reading, instruments. The former set of instruments are Mascart magnetographs, the latter are said to be of a similar type. The instruments for absolute observations are illustrated in a plate at the end of the volume. The declination and horizontal intensity are observed with an instrument due to Prof. Tanakadate, possessing some unusual features, of which a fuller description is given in the *Proc. R.S.E.* for 1884–6. The times required for taking the several observations are given as: declination, 5 minutes; horizontal force, 20 minutes; inclination, 20 minutes! Absolute observations are taken on only one day a month, but the operations are repeated several times; there are also monthly determinations of the curve scale values. The necessary temperature corrections are based on direct experiments on one occasion when the magnetograph room was artificially heated. Hourly measurements are made of all the magnetic curves and the results appear in tables, one for each element for each month. In addition to the hourly readings, each table gives the daily mean, maximum, minimum and "range" (maximum less minimum); it gives also the monthly mean for each hour of the day, and the means for the month of the diurnal maxima, minima and "ranges." The general character of each day, whether quiet or more or less disturbed, is also noted. The monthly means are summarised on p. 59, and there are curves of diurnal variation for each month and for the year.

The mean monthly diurnal variations are also analysed in Fourier's series. The fact should be noted that the "mean range" of any element for each month being the mean of the differences between the daily maxima and minima, irrespective of the times of their occurrence, is necessarily larger than the range shown in the mean monthly diurnal variation; it may be largely influenced by the occurrence of magnetic disturbances. For instance, the "mean range" in the horizontal force is given as greater in December than in any other month except April, but the value in December is considerably affected by the occurrence of two or three exceptionally large "ranges." The mean monthly diurnal variations are less exposed to accidental influences; their nature is most easily followed in the curves. The amplitude of the regular diurnal variation in both declination and horizontal force appears least in November. The amplitudes in January appear surprisingly large compared to those in the last three months of the year.

The atmospheric electricity installation consists of a Kelvin water-dropper, the discharge tube of which projects "about 2 metres" at a height of 1·7 metre above the ground. This is connected to the needle of a quadrant electrometer, the quadrants of which are connected the one pair to the positive the other pair to the negative pole of a battery of water cells, the centre of which is to earth. This seems the same arrangement as at Kew. The scale value of the curves is determined weekly. The hourly readings are recorded in tables, one for each month. The daily means, maxima, minima and "ranges" are recorded as in the magnetic tables, also the nature of the daily weather. Hourly means are also given for each month, but in forming these a considerable number of individual results are omitted as being abnormal. Amongst the values omitted are most of the negative potentials, and some entire days are excluded on which negative readings were numerous. The measurements of potential being all given in volts, one can follow readily the annual change, which is more than usually pronounced. Thus the mean potential for the year being 47·2 volts, the mean voltage for the three months December to February was 93·2, while that for the three months July to September was only 9·0; the maximum monthly mean was 112·8 in December, the minimum 6·9 in August. It may be added that the exceptionally low value in August appears in no way due to exceptional occurrences of negative potential.

The mean diurnal variations for the several months are illustrated by curves. As usual there is a marked tendency to a double diurnal variation; but the principal maximum occurs between 6 and 8 a.m., instead of, as is customary, in the late evening. Further, the principal minimum is found, the whole year round, in the early afternoon, usually from 2 to 3 p.m. These results possess a special interest from their apparent irreconcilability with views due to Chauveau which have recently met with considerable recognition.

Another notable feature is the size of the mean diurnal variation. The largest mean hourly value of the potential is in most months some four or five times the smallest; for instance, amongst the mean hourly values in December the maximum was 187·6, the minimum 42·1, while the corresponding values in August were 13·7 and 2·8. The peculiarities shown by the atmospheric electricity results at Tokio are, to a considerable extent, manifested by observations made during a series of years in the Batavia Observatory, but though Batavia is much nearer to the equator than Tokio, the results at the latter station show the greater departure from those ordinarily recorded in Europe.

What has been said will suffice to show the interest of the volume, and the evidence it affords of the progressive spirit in Japanese science. The continuance of the observations, and also of the practice of describing them in English (sometimes with Japanese equivalent), is much to be desired. There are, however, one or two points where some friendly criticism may be offered. The variation in the scale value of the horizontal force curves —from $10^{-6} \times 69$ to $10^{-6} \times 57$ C.G.S. units for 1 mm.—is excessive; and the vertical force scale values show even larger variations (1 mm. $= 10^{-6} \times 82$ in April, $10^{-6} \times 239$ in June, and $10^{-6} \times 79$ in November). Changes such as these, unless produced designedly at known times, introduce uncertainties into at least the annual variation in the amplitudes of the diurnal inequalities. Again, the temperature coefficients are so large for both the horizontal and vertical force magnetographs that appreciable uncertainty must be introduced into the diurnal variations unless the changes of temperature are known with extreme accuracy. Under such conditions, the employment of *six* significant figures in the tables of monthly means of the diurnal variations of the force components seems hardly well advised.

In the case of atmospheric electricity, 1 mm. of curve ordinate answered, on the average, to 3·86 volts in February, 1·15 in August and 2·69 in December. If, as one would rather *infer* from the preface, the number of battery cells in use varied from 30 to 50, one would not be surprised at a considerable change in the scale value, and it would be only good policy to have the scale contracted in winter when the mean potential is large. The changes recorded in the scale value seem, however, too large to be wholly accounted for in this way, and they do not exhibit so regular a fluctuation as to suggest design. A little further information on these points would enable the critic to pronounce with greater assurance on the value of the results.

C. CHREE.

STORAGE RESERVOIRS.

Reservoirs for Irrigation, Water-Power, and Domestic Water-Supply. By James D. Schuyler, M.Am.Soc. C.E. Pp. xviii+414. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1901.)

THE title-page of this book states that it also contains "an account of various types of dams, and the methods and plans of their construction; together with a discussion of the available water-supply for irrigation in various sections of arid America; the distribution, application, and use of water; the rainfall and run-off; the evaporation from reservoirs; and the effect of silt on reservoirs." The book was, accordingly, designed to embrace all the main questions relating to the construction of reservoirs, together with the distribution and use of the water stored up; but in reality the different methods of construction of reservoir dams, descriptions of numerous examples in the United States, and references to the works required for several projected reservoirs constitute the principal subjects dealt with. The most remarkable feature, however, of the book is the abundance of views of reservoir dams, reservoirs, and proposed sites for reservoirs, comprising a large proportion of the one hundred and eighty-three illustrations, which should prove very attractive to the general public; whilst the plans and sections of dams and other contingent works, maps of reservoirs and of proposed sites for reservoirs with contour lines, and twenty-five folding plates, in an appendix, of reservoir sites in California and the Lahontan and Arkansas River basins, and of the Sun River system of reservoirs in Montana, will appeal mainly to engineers.

The book is divided into only six chapters, treating respectively of Rock-Fill Dams, Hydraulic-Fill Dams, Masonry Dams, Earthen Dams, Natural Reservoirs, and Projected Reservoirs, to which an appendix is added containing particulars of reservoir surveys and designs in California, Nevada, Colorado, Montana, Utah, New Mexico, and Arizona, and the cost of reservoir construction per acre-foot in the United States and other countries.

Rock-fill dams of a temporary character, formed of timber cribs filled with stone, were originally used in California for impounding water for mining purposes; and subsequently more serviceable and more watertight dams were obtained by introducing some dry stone walling in front of a loose stone embankment, faced with two or three thicknesses of planks. Since then the loose stone embankment has been made more durable by facing it with asphalt concrete, or Portland cement concrete, or steel plates, laid on a sloping dry wall, or by introducing a central core of steel plates, or by a facing of masonry backed with earth, or by facing it with earth. Examples of these various types of rock-fill dams are described in the first chapter; and the extent of irrigation effected by means of the water stored up by these dams is indicated. Naturally dams of these economical types, imposed sometimes by the inaccessibility of the site and the necessities of the case, and occasionally very carelessly constructed, have not been exempt from failures, their bursting having been sometimes accompanied by disastrous results.

In a few instances, reservoir dams have been formed in the United States by directing a powerful jet of water against the upper slopes of a valley, and thus causing the materials scoured from the hillsides to be conveyed by the water to the site of the dam proposed to be constructed across the lower part of the river valley. By suitable arrangements, the stream of water from the issuing jet both conveys the materials by gravity to the required site, depositing them along the lines of the two slopes which are kept higher than the centre of the embankment, and consolidates these materials in position, the larger stones being dropped at the sides, and the finer materials being carried towards the centre of the dam in drawing off the water through standpipes. The best materials for this hydraulic-fill construction are a mixture of soil, sand, and gravel of various sizes; and examples of dams in the United States constructed successfully by this method are given in the second chapter. Both rock-fill dams and hydraulic-fill dams exhibit the peculiar resource and boldness of American engineers; though Canadian engineers have resorted to the hydraulic system for the formation of permanent embankments on the Canadian Pacific Railway, in place of the temporary wooden trestle viaducts provided at the outset for crossing valleys and gorges rapidly and economically.

The conditions of stability of masonry dams, involving a solid rock foundation, and a well-established profile in section varying with the height, have been so fully recognised for many years past, and any considerable departure from them appears so certain to result in failure, as illustrated by the history of the Bouzey dam in France, which gave way in 1895, that there might seem to be little scope for novelty in such constructions. Whereas, however, in European practice the curvature of a masonry dam in plan has generally been merely regarded as conferring an additional element of stability on the dam, American engineers have not hesitated to rely largely on the arched form for the stability of some dams, which have been given such slight sections that they could not possibly have resisted the water pressure unaided. This is exemplified to some extent by the slender Sweetwater dam, 90 feet high and only 46 feet thick at the base, and curved to a radius of 222 feet; and more especially the Bear Valley dam, which, though only 64 feet high, has been made unprecedentedly slight with a thickness of only 8½ feet 48 feet down from the top, where it rests on a masonry base 13 feet thick, so that its section is absolutely at variance with correct principles, and it would long ago have been swept away had it not been curved up-stream with a radius of 335 feet. The Zola dam in France was constructed about 1843, twenty-three years before French engineers inaugurated the correct profile for masonry dams by the completion of the Furens dam with ample stability in 1866, though retaining a maximum head of water of 164 feet; but unlike this latter dam, the Zola dam owes its stability entirely to its arched form in plan of 158 feet radius, coupled with the very short length of 23 feet at its base; for the Zola dam, though 120 feet high and 19 feet thick at the top, is only 49 feet thick at its base, showing that no approximation to the correct section had been reached at that period for what the author calls "gravity dams," supporting the water pressure by their weight alone.

Several examples of masonry dams in the United States are described and illustrated by views, sections, and plans; whilst short references are made to the most notable masonry dams in other countries. La Grange dam in California, for diverting the water of the Tuolumne River for irrigation, 125 feet high, resembles the Vyrnwy dam in section, the outflow in both cases taking place over the top of the dam. The San Mateo concrete dam in California, designed to have a height of 170 feet, but stopped at present at 146 feet, and a total length at the higher level of 680 feet, has a bottom width of 176 feet, and is arched up-stream with a radius of 637 feet; and the reservoir formed by the completed dam will have a capacity of 29,000 million gallons. The Ash Fork steel dam, 184 feet long and 46 feet high for a central 60 feet, built in 1897 across Johnson canyon in Arizona, is a novel type of dam, constructed with triangular steel frames covered with steel plates; but the experiment has not proved satisfactory, as the steel dam leaks considerably at its junctions with the masonry buttresses at both ends, and with the concrete foundation at the base. An interesting form of the failure of a masonry dam is furnished by the history of the Austin dam in Texas, illustrated by views, 1091 feet long and 68 feet high, built in 1891-92 and founded on limestone rock. In April, 1900, an unprecedented flood of the Colorado River raised the water-level of the reservoir 11 feet above the crest of the dam; and 500 feet of the dam slid forward on the foundation about 60 feet down stream, though a flood in the previous summer, raising the water 9⅕ feet above the crest, had passed down without injuring the dam. Another interesting feature of this work was the filling up of over two-fifths of the reservoir capacity with sand and silt in four years, owing to the yearly discharge of this sediment-bearing river amounting to about forty times the capacity of the reservoir.

Some earthen dams constructed in California and Colorado, for forming reservoirs for irrigation, are described in a short chapter. Natural reservoirs in the great plains to the east of the Rocky Mountains, formed by depressions collecting the storm waters from the adjacent districts and devoid of an outlet, can be readily utilised for irrigating arable lands at a lower elevation; and examples of such reservoirs are described in the fifth chapter. The final chapter is devoted to schemes for reservoirs, mainly in California, Colorado, Montana, New Mexico, and Utah, and like the preceding chapter possesses mainly a local interest; but the descriptions serve to show what a field there is in these Western States for such works, and what a large development of irrigation, with its attendant benefits, may be accomplished in these regions.

OUR BOOK SHELF.

The Anatomy of the Cat. By Jacob Reighard and H. S. Jennings. Pp. xx + 498. (New York: H. Holt and Co., 1901.)

YET another book upon the cat! With the great treatise of Strauss-Durckheim, and the books of Mivart, Wilder and Gorham, published, and the great work of Jayne in course of publication, there would seem little room left for this now before us. When, however, it is remembered that the treatise of the first-named author is not available for American students; that, like that by Wilder, it deals only with parts of the animal described; that the late Dr. Mivart's book, rather a general treatise on mammalian morphology than a special one upon the cat, fails completely in most parts where anatomical detail peculiar to this animal is concerned; that the book by Messrs. Gorham and Tower, though a laboratory treatise, is but brief—it will be clear that ample room is left for the work under review, which is designedly a laboratory book, giving a complete and well-balanced description of the facts of anatomy of the animal concerned "in moderate volume and without extraneous matter."

There are in all 472 pp. in the book, of which the appendix of 44 pp. is wholly given to directions for practical dissection. The body of the work consists of brief but concise descriptions of the organic systems taken in order—the skeletal, muscular, visceral, circulatory, nervous and sensory systems (the latter with the integument) being in turn dealt with. Anatomical characters are alone recognised; neither those histological nor which concern growth stages of even the bones are in any way given; nor is there any reference to literature beyond brief mention of the works by the aforenamed anatomists and some few others, together cited in the preface. Our authors have done well to consult the myological observations of Windle and Parsons, but they have omitted to even record the important work upon the morphology of the digestive tract of the cat, by Dr. Franklin Dexter, of the Harvard Medical School, which has been progressing side by side with their own.

This book is what it professes to be—a laboratory treatise, clear, deliberate and clean cut, in its style and method most nearly akin to the didactic laboratory treatises of the late Milnes Marshall, so fully in vogue by the type of student who cares only for facts. It is based upon an earlier account of the anatomy of the cat, designed by the senior author for class use in the University of Michigan in 1891-92. The junior author is responsible for its completion for publication, and the 173 text illustrations, which, though clear, are in no way remarkable, have been prepared under his supervision by his wife.

The chief novelty of the book is a system of nomenclature, based upon that proposed in 1895 by the German Society of Anatomists. A large section of the preface is devoted to a discussion of this and cognate subjects; the use of Latin terms in their English form, and the significance of topographic terms and terms of precise orientation, being among the more important topics discussed.

We are informed that the notes which furnished the basis of the book have been used with success in four or five of the American Universities, and although among English teachers, who prefer the rabbit to the cat for educational work, the book will be little in demand, it will be welcome beyond those upon the cat hitherto in use on account of its accuracy of descriptive detail and uniformity of treatment.

Essays in Illustration of the Action of Astral Gravitation in Natural Phenomena. By William Leighton Jordan, F.R.G.S., M.R.I., Assoc.Inst.C.E., F.S.S., F.S.A., F.R.M.S. Pp. xv + 192. (London: Longmans, Green and Co., 1900.)

WHEN an author puts forward perfectly new views in opposition to those generally accepted, using technical terms like *force* and *energy* in several new senses, it is very difficult to find out exactly what he means. In his definitions he says that gravitation resists all impressed motion with a force as the square of the velocity. He defines *vis inertiae* as the force with which matter resists motion. It is as the mass multiplied by the square of the motion resisted. After defining momentum, he says that it is resisted by the inertia of matter in its origin and in its progress, whereas Newton's first law of motion supposes inertia to resist its origin but to sustain its progress. The author's membership of many learned societies might warrant the belief that he has some meaning in what he says, but it is certainly very carefully concealed.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The National Antarctic Expedition.

I HAVE recently been made acquainted with certain hypotheses which are believed to explain the motives which induced Prof. Gregory to resign the position of scientific director of the National Antarctic Expedition. Thus, it is commonly believed that he was influenced by his family and friends. Indeed, the opinion has recently been expressed that I was, perhaps, the cause of his withdrawal, or that, at least, I advised it. It is impossible to imagine how such an opinion can have arisen if my letter to the Fellows of the Royal Society had been read with any attention, unless, indeed, I have failed to give a fair and accurate account, in spite of most serious efforts, put forth with a grave sense of responsibility.

I am, however, now able to set the matter at rest by a quotation from Prof. Gregory's letters received since the circulation of my account of the negotiations. I am quite sure that Prof. Gregory would have no objection to this use of his words in order to confront the unfounded rumours which have obtained currency.

It may be remembered that after the meeting of the Joint Committee on March 5, at which Major Darwin's proposed changes in the conditions offered to, and accepted by, Prof. Gregory were approved, although I had strongly opposed the introduction of any alteration whatever, "I wrote to Prof. Gregory a full account of what had happened, carefully explaining that his representative and many of his friends supported the changes, that I had confidence that the proposal was made to enable the Geographical Society to accept the instructions, and that it was not intended to prevent, and, I believed, would not prevent, his being landed" (p. 6 of my letter).

I have now received two letters from Prof. Gregory, one written on April 16, before he had received mine, the other on April 23, after he had received it.

In the former he says: "I hear that the Joint Committee has accepted some of Darwin's amendments; but as I do not know what they were I can form no opinion. But ——, —— and —— say they make no difference. I hope not."

In the latter, written in reply to my letter, he says: "Very many thanks for your fight against Darwin's amendment, which I should not have accepted had I been in London or been advised of it by cable. However, I suppose it is now too late to go back on it; and as it has [been] accepted for me I must trust to luck."

Later on in his letter the explanation of his resignation becomes perfectly clear; indeed, he asks me to make it known. In the event of the President of the Geographical Society declining to sign the instructions, he says: "*Please let it be known that, except for a modification backward of Darwin's amendment, I will not accept another change.*"

Between my letter describing the meeting on March 5 and May 15, when his final resignation was known, I held no communication of any kind with him. But others had communicated those further changes which he was determined not to accept.

It must be clear to any one who will read the history of the negotiations carefully, that he thought, and had good reason to think, that he was being trifled with, and felt that the time had come—to a less patient man it would have come long before—when he would no longer submit to the vigorous attacks of the Royal Geographical Society and the weak, half-hearted defence of the Royal Society.

* * * * *

A few hours after the above words were written a letter arrived from Prof. Gregory dated May 5, just after he had received the cable from the new Committee of six. The letter indicates clearly the reasons which induced him to withdraw, and I therefore quote several passages from it. The letter was written hurriedly, and not intended for publication; but I know that Prof. Gregory would assent to my action, pursued as it is with the object of preventing the misinterpretation of his motives. A few unimportant verbal changes have been made.

"You at least," he says, "will not have expected me to accept the cabled terms. I was not surprised at them; only surprised that the Royal Society had given way apparently so readily and that I heard the result a month earlier than I expected."

"The terms proposed appear to me, as far as I understand them from the cable, a complete surrender of what the Royal Society's representatives declared in February was essential to the proper execution of the magnetic work. The position gives no power to secure a fair opportunity for work to the man who would have to bear the blame for scientific failure."

"To accept responsibility without adequate power is a false position which is almost sure to lead to trouble. No man has a right to take such a position. As I do not think the powers are adequate to the responsibilities, it is my simple duty to withdraw. I hope the Royal Society will find a better man, who will be satisfied that he can make the Expedition a scientific success on the instructions given. I am not; therefore I must withdraw my provisional acceptance of the appointment."

"It will be difficult to prevent my withdrawal being misinterpreted. I had thought of cabling to ask you to publish an explanation, but thought it best to leave you to act as you thought best. I can absolutely rely on your judgment, and know you will have done anything necessary to repel insinuations."

I have done my best to prevent Prof. Gregory's motives from being misunderstood, and it is with the same object that this communication is now written and accompanied by quotations from his letters.

He concludes with a reference, which is far too appreciative, to the support which—unfortunately for the scientific prospects of the expedition and, I must add, unfortunately for the credit of the Royal Society as the guardian of the interests of science—received, at the later stages of the negotiations, the help of so small a proportion of my colleagues.

Oxford, June 11. EDWARD B. POULTON.

A Raid upon Wild Flowers.

PROF. L. C. MIALL, in the last number of NATURE, makes very definite and serious charges against the organisers of the vacation course for Essex teachers in the New Forest. As author of the programme so severely, and, as I contend, unfairly, criticised by your correspondent, I should be glad to be allowed an opportunity for reply.

The programme, as you will see by the copy enclosed, consists of two parts, the first dealing with a series of Saturday afternoon botanical rambles in our own county and the other with the proposed vacation course to be held at the New Forest. The first is of a pioneer character, and is open to all teachers whether they are familiar with botany or not, while the vacation course is organised for those of our teacher-students who have already received one, two or more years' instruction in laboratory and field-work in botany at the central institution here. For this course special application must be made to the committee.

From a perusal of the programme Prof. Miall accuses the Committee for Technical Instruction in Essex with organising a raid in the New Forest especially upon wild flowers tending to extinction, and bases his charge upon certain alleged facts. Your readers are told that with respect to these rare plants our intention is to collect, &c., "not only single specimens but duplicates for special fascicles." There is no such reference in the programme of the vacation course in the New Forest, but in a note at the end of the Saturday afternoon programme occurs these words.

"Opportunity might be taken, during the course of the Saturday rambles, of commencing a school herbarium, or collection of dried plants illustrative of the flora of collector's own district. A type collection would naturally be arranged in botanical order, but duplicates might be used for special fascicles representing, for example, 'meadow plants,' 'cornfield weeds,' &c."

The letter continues—"Local guides are to direct them to the last retreats of the rare plants of the New Forest." This, too, is a mistake. In the Saturday afternoon rambles we are to be accompanied by local guides whose names and addresses are given in the programme, but no such arrangements were made for the New Forest. It is true that I sought the sympathy of local naturalists, and, indeed, so anxious was I to prevent even the suspicion of "raiding" that I wrote to the Rev. J. E. Kelsall, the local representative of the Selborne Society, whose strong views on the preservation of the plant and bird life of the New Forest are so well known, to tell him of our proposal and to assure him that our chief object was the study of living plants, and that if we discovered anything rare, or even scarce, it would be left untouched by our students; and I thought that the publication of the fact that Mr. Kelsall and Mr. Dale, secretary of the Hants Field Club, might be able "to accompany the party on one or more of its rambles" a sufficient guarantee that the rights of wild plants would be respected.

Furthermore, on the title page of the vacation course programme, p. 9, and printed in conspicuous black type, is the following notice: "Members of the party will, of course, refrain from uprooting rare or scarce specimens." Yet Prof. Miall alleges "there was no such restriction in the printed programme"!

In the daily itinerary as printed in the programme reference is made to the character of the scenery, the soil and surface geology, the prevailing vegetation, and to some of the rare plants growing in the neighbourhood. From what we have already shown it could hardly be our intention to raid these rare plants, and especially as several of those mentioned will be out of flower in August. Indeed, so particular are we in these rambles that the needless uprooting even of the commonest weed is discountenanced, as may be seen in the further notice on p. 3 of the programme.

In comparison with such a particularly odious charge as plant extermination, the other strictures of your correspondent's letter are, of course, scarcely worth noticing; yet even with respect to these I cannot resist pointing out that Prof. Miall's statements are strangely at variance with the actual facts. For example, he writes: "It is enough to condemn the programme as an educational project that novices knowing little or nothing of field-botany are set to study the subspecies of brambles." But does the programme so recommend? It distinctly says in reference to this (p. 18), that "their identification will give capital exercise in critical observation to the *more advanced worker*."

The real object of these field-studies, as stated on the front page of our programme, is to give teachers "an insight into the way in which plants grow, especially in their relations with their environment—the influence of external conditions, such as light, heat and moisture, upon their form, the mutual relationships between plants and animals and the influence of one organism upon another," and is in no way connected with collecting in the sense used by Prof. Miall. The vacation students have varied interests—flowering plants, algæ, leaf-fungi, &c., and the evenings are to be spent in discussing "the most interesting of the objects collected" and on the "preservation" of such as may be useful for class-work in the winter courses. Readers of NATURE will understand that work of this sort does not mean the collection of rare flowering plants.

Perhaps because of the peculiar gravity of the charge I may, in conclusion, be allowed to introduce one personal note into the reply. I should like to say that although I have conducted field studies in botany for the last twelve years (including two summer courses at the New Forest), yet, as it happens, I am no collector myself, and have never made what botanists would call a collection of dried plants in my life. Furthermore, I have never possessed, or even "coveted," a single specimen of a rare British plant. On the contrary, my sympathies are, of course, entirely with those who are opposed to any interference with our native flora, and I do most strongly protest against this attempt of Prof. Miall to connect in any way whatever our botanical work with such objectionable practices.

I should be glad to send a copy of the programme to any one who may care to see it. DAVID HOUSTON.

County Technical Laboratories, Chelmsford, June 10.

Emanations from Radio-active Substances.

IN a recent number of the *Comptes rendus* of the Paris Academy (March 25) an account appeared by MM. P. Curie and A. Debierne of the production of a radio-active gas from radium. In their experiments some radium was placed in a glass vessel and the air exhausted by means of a mercury pump. It was found that the vacuum steadily decreased, due to the giving off of a gaseous substance from the radium. A small amount of the gas thus collected was found to be strongly radio-active. It caused phosphorescence in the glass tubes over which it passed, and in course of time blackened them. Substances exposed in the gas became themselves temporarily radio-active.

Some time ago (*Phil. Mag.*, January and February 1900) I showed that thorium compounds continuously emitted radio-active particles of some kind, which preserved their radio-activity for several minutes. This emanation possessed the remarkable property of causing all bodies, in contact with it, to become themselves radio-active. In an electric field the excited radio-activity could be concentrated and confined to the negative electrode. In this way I was able to make a fine platinum wire become a very powerful source of radiation.

The excited radio-activity gradually diminished, falling to half its value in about twelve hours. The specimen of impure radium then in my possession gave out no emanation and caused no excited radio-activity. Later, Dorn, using the same methods, showed that a preparation of radium from P. de Haen, Hanover, gave out an emanation similar in properties to thorium. With a specimen of radium obtained from the same source I have found that the emanation given off is small at atmospheric temperature, but can be enormously increased by slightly heating the radium. In this way I have obtained ten thousand times the amount of emanation given off at ordinary temperatures. An account of these experiments is given in the *Physikalische Zeitschrift* (April 20).

By passing the emanation with a current of air into a closed vessel, and then closing the openings, the emanation remains radio-active for a long time. The radio-activity decreases slowly, but is still quite appreciable after an interval of one month. M. and Mme. Curies, some time ago, stated that they had obtained a radio-active gas which preserved its activity for several weeks; this is possibly identical with the emanation.

Up to this point I had been unable to obtain any definite evidence whether the so-called emanations were vapours of the radio-active substances, radio-active gases, or radiating particles large compared with a molecule. The radium and thorium, when placed in an exhausted tube, gave no appreciable lowering of the vacuum, and no new spectral lines could be observed. The quantity of substance emitted was too small to examine by chemical methods.

Quite recently, however, some light has been thrown on the question of the nature of these emanations by examining their rate of diffusion by an electrical method. In these experiments I have been assisted by Miss H. T. Brooks, and the results point to the conclusion that the emanation from radium is in reality a radio-active gas, with a molecular weight probably lying between 40 and 100.

There is one distinct feature which distinguishes the emanations from radium and thorium. The thorium emanation loses its radio-activity in a few minutes, while the excited radio-activity due to it lasts several days. The radium emanation, on the other hand, preserved its radiating power for several weeks, while the excited radio-activity due to it disappears in a few hours. In the following experiments it was only possible to experiment with radium emanation, on account of the rapid decay of radio-activity of the thorium emanation.

The diffusion apparatus was similar to that which had been employed by Loschmidt in 1870 in his determinations of the coefficients of interdiffusion of gases.

A brass cylinder, 73 cm. long, 6 cm. in diameter, was divided into two equal parts by a metal slide, which could be opened or closed. The ends were closed by insulating ebonite stoppers, through which passed central rods half the length of the tube. In order to introduce the emanation into one half of the cylinder the slide was closed, and a slow current of air, which had passed over slightly heated radium and thus carried the emanation with it, was passed through the cylinder. When a sufficient amount had been introduced the current of air was stopped and the openings closed. After standing for an hour or more the slide was opened, and the radio-active emanation slowly diffused into the other half of the cylinder. The amount of emanation in each half of the cylinder after any interval was tested by observing the current through the gas, when a suitable P.D. was applied, by means of an electrometer. The current is carried by the gaseous ions which are continually produced by the radiation from the emanation. From these observations the coefficient of inter-diffusion of the emanation into air at atmospheric pressure and temperature can be readily deduced. The experiments are, however, complicated by the excited radio-activity on the electrodes, which must be taken into consideration.

So far as the observations have gone up to the present, the coefficient of diffusion of the emanation into air has a value between 0·10 and 0·15, and probably nearer the former. Now the coefficients of inter-diffusion of some known gases and vapours into air have been determined. The following examples have been taken from Landolt and Bernstein's tables:—

Gas or Vapour.	Coefficient of Diffusion into Air.	Molecular Weight.
Water vapour	0·198 ...	18
Carbonic acid gas	0·142 ...	44
Alcohol	0·101 ...	46
Ether	0·077 ...	74

In the above we see that the coefficients of diffusion follow the inverse order of the molecular weights. In cases of the simpler gases it has been shown experimentally that the coefficient of inter-diffusion is approximately inversely proportional to the square roots of the product of the molecular weights. If we apply these considerations to the emanations we see that it is a gas or a vapour of molecular weight (allowing a wide margin) probably lying between 40 and 100. These numbers exclude the possibility of the substance being a vapour of radium, for it has already been shown by M. and Mme. Curie that the atomic weight of radium is greater than that of barium.

We must, therefore, conclude that the emanation is in reality a heavy radio-active vapour or gas.

On account of the rapid decay of the radiating power of thorium emanations it is not possible to determine its coefficients of diffusion in the same way; but special experiments show that it diffuses rapidly, and is also probably gaseous in character. The physical properties of these emanations or gases are most remarkable. The radium emanation not only continues for long intervals to be a source of radiation which is apparently similar in character to easily absorbed Röntgen rays, but in some way manufactures from itself a positively charged substance, which travels to the negative electrode and becomes a source of secondary radio-activity.

Space is too short to enter into the interesting question of the possible explanation of these complicated phenomena.

McGill University, Montreal, May 30. E. RUTHERFORD.

Long-tailed Japanese Fowls.

A LITTLE while ago in your columns Prof. Lankester referred to this breed as "a magnificent sport," and considered the occurrence of genius in mankind as a case of the same kind. In Newton's "Dictionary of Birds," article "Feather," it is stated that in these Japanese poultry the moult is checked or prevented by some means unknown to Europeans. It is obvious that the latter statement, if correct, is not compatible with Prof. Lankester's description. If the breed really arose as "a magnificent sport," I presume that the excessive growth of the tail coverts would be due to a spontaneous variation, and not to some artificial method of preventing the annual moult. After a great deal of trouble I have succeeded in obtaining evidence, which seems to me unimpeachable, concerning the means taken by the Japanese to produce this extraordinary elongation of feather in the cocks of the breed in question.

I will quote the words of my informant. He writes:—"With regard to the treatment of these birds, in order to ensure very great length of tail, they ought after they are six months old to be kept on a perch as much as possible, and the tail feathers should be pulled gently every morning, grasping the centre bone-like part firmly with the finger and thumb, and, pressing steadily, draw downwards towards the tip, each feather being done several times; this softens the quill and causes it to lengthen. They do not moult the feathers, but if one or more come out others immediately grow in their place. The Japs themselves, those who take great pride in their birds, always roll the long feathers up, like a lady rolls up her hair, and tie them, whenever they are let off their perches to walk about, which is about twice a day for an hour at a time. . . .

"I have often seen them thus treated in Japan, and the man who brought mine over treated them in this way on the voyage over, and I sent them (to purchasers) in their regular perch cages."

I think this, being the evidence of direct observation, is enough to prove that the length of feather in these birds is not correctly described as a "sport," but has been produced by special artificial treatment. The effect of the treatment is doubtless to irritate the papilla from which the feather grows, and so cause increased growth, rather than to soften and lengthen the already formed quill. The feathers appear to grow throughout the year, so that when the moulting season is reached they are not shed, but continue growing.

There is no doubt that the peculiarity is to a certain extent hereditary, but extreme length of feather cannot, I believe, be produced without the special treatment. These fowls have been bred in England, and I have seen specimens which had tail coverts (and also hackles) longer than those of any European breed, but so far as I know no specimens bred in Europe have produced the extraordinary length of feather that is known to occur in Japanese specimens, for example in the two stuffed specimens in the hall of the Natural History Museum. It seems to me reasonable to conclude that the hereditary effect is due to the artificial irritation applied to a long succession of generations.

Penzance, June 5. J. T. CUNNINGHAM.

Variation in a Bee.

ON September 24, some years ago, I collected at Mesilla, New Mexico, four examples of a wild bee of the genus Epeolus, the species being probably identical with *Epeolus bardus* of Cresson. In every one of these specimens the second transverso-cubital nervure is incomplete, its lower half being wanting, on one or both sides. In one example only is the nervure incomplete on both sides; in the other three it is incomplete on the right side only. Such aberrations are not very uncommon among bees, but they usually occur in single examples, and this is the best instance known to me of their being inherited by a number of individuals. What is here clearly a sport seems in a fair way to become a racial character, and we seem to have a good example of Bateson's "discontinuous variation." In the genus Halictus certain species have only two submarginal cells, instead of the usual three, and the same is true of Andrena. These peculiar species are related to different groups of the genera to which they belong, so that if it is proposed to regard them as pertaining to distinct subgenera (or genera) by reason of their venation, it becomes necessary to propose several subgeneric names instead of one, because of the independent evolution of the species. That this evolution has resulted from the perpetuation of sports such as that described above we can hardly doubt, but we are not thereby compelled to admit that it may not also be beneficial to the species.

Foreign Oysters Acquiring Characters of Natives.

THE facts contained in Mr. Tabor's letter, however interesting, supply no evidence for or against Lamarckism. When at Whitstable, the individual French oyster has certain characters impressed upon it by its environment. The next generation, when compared with the natives, show certain peculiarities, such as greater thickness of shell and greater growing power. But this also we are able to interpret as the reponse of the individual to the environment. If the peculiarities appear in many successive generations, the same explanation will account for the facts. If, however, Lamarckians could show that the effect of the environment, as the generations succeed one another, is cumulative, that the characters in question become *progressively* accentuated, then they would prove their case. But it does not appear that they have any such evidence at their command. F. W. HEADLEY.

Haileybury College, Hertford.

ITALIAN EXPLORATION IN ARCTIC REGIONS.

THE recent success of the Duke of the Abruzzi's expedition, which carried the Italian flag nearer the North Pole than ever flag flew before, has doubtless prepared a public in Italy for the literature of Polar exploration. The firm of Hoepli, who have conferred many favours on Italian-speaking geographers, have just published a history of Polar exploration in the nineteenth century by Signor Hugues.[1] The book makes no claim to originality, being merely a condensed popular description of the Polar voyages of the late century, and although more detailed on account of the shorter range of time dealt with, and coming down to the year 1900, it cannot compare with General Greely's compact handbook as a work of reference for the student. The most serious drawback is the want of a bibliography or a uniform

[1] "Luigi Hugues—Le Esplorazioni Polari nel Secolo XIX." Pp. xx + 374. Maps and Illustrations. (Milano: Ulrici Hoepli, 1901). Price 12 lire.

system of acknowledging sources of information. Another, which strikes an English reader, is the curiously unfamiliar aspect of well-known names of people and places in their Italian form—Giovanni Ross and Giuseppe Wiggins, Terra del Re Guglielmo and San Giovanni de Terranuova require some thinking over. Where so many personal names are foreign to the author, misprints may easily escape detection, and in the index a cursory inspection reveals about a dozen slips, of which the worst are Gordfelow for Goodfellow, and Newes for Newnes. Probably no English author could handle more than 600 foreign names with fewer accidents. Except for a tangle of dates on p. 98, and the necessary baldness in the treatment of some picturesque episodes induced by brevity, the narrative is clear, interesting and, so far as we can test it, correct. Most space is, of course, given to the Arctic regions; but the history of South Polar voyages is also summarised.

The members of the Italian Arctic expedition had a magnificent reception in Rome on January 14, the description of which, together with the addresses of the Duke of the Abruzzi and Captain Cagni, occupy practically the whole February number of the *Bollettino* of the Italian Geographical Society. The hall was splendidly decorated with flags and Arctic trophies; and the King and Queen of Italy, with other members of the Royal family, the great officers of State and the Diplomatic Corps, as well as the heads of the scientific bodies in Rome, were present.

The Duke of the Abruzzi described the equipment of the expedition and the voyage of the famous whaler *Jason*, renamed the *Stella Polare*, to her winter quarters in Teplitz Bay; and after Captain Cagni had told the story of his great sledge journey over the ice, H.R.H. resumed the narrative of his sojourn at the base and the return of the party to Europe.

The following is a brief summary of the facts:—

The *Stella Polare* left Archangel, where she had called for dogs, on July 12, 1899, and, after some delay in the ice, passed Cape Flora, in Franz Josef Land, on the 26th, sailed up the strait named by Jackson the British Channel and along the shore of the Queen Victoria Sea to a point in 82° 4′, just north of Cape Fligely on Prince Rudolf Island, which was reached on August 8th, after a good deal of trouble from the ice. Teplitz Bay, in 81° 47′, was chosen for wintering the ship; the dogs and stores were landed there, and the ship, having been damaged on September 9 by an ice-pressure, the party was obliged to land and live on shore. During the winter the Duke of the Abruzzi was severely frost-bitten in the hand and was obliged to abandon his intention of accompanying the sledge expedition to the north in spring. The command of this expedition accordingly devolved on Captain Cagni. The sledges used were of Nansen's pattern; the sleeping bags for the men were made of reindeer skin; pemmican was the chief food relied on, and petroleum was used for cooking. The expedition was marshalled in three divisions, each consisting of three men and four sledges, on which were placed 180 rations for men and 1150 for dogs. The provisions of the first division would suffice for the whole party for fifteen days after leaving the island, when the people of that division would return. The provisions of the second division would supply the two remaining groups for fifteen days more and then suffice to allow its members to return to the base, while the third group with their intact store of provisions should be able to push on for fifteen days more, or forty-five days from the base, before requiring to return.

In some preliminary sledge trips in February a temperature descending to −52° C. (−62° F.) was recorded, this being the lower limit of the graduation of the minimum thermometer. The start for the real attempt on the pole was made on March 11, 1900, when the caravan of three parties struck out boldly across the sea-ice, bound north, Captain Evenson and two sailors accompanying the expedition for two days with a thirteenth sledge. The advance at first was slow, on account of bad weather and rough ice. On March 22 the first division, consisting of Lieut. Quirini, the guide Ollier, and the engineer Stökken, left to return to Teplitz Bay. This party has never since been heard of, and there is little doubt that all three have perished. On March 31 the second group went back, and Captain Cagni continued on his way with three companions, Italian Alpine guides named Petigax, Fenouillet and Canepa. By sending back the other parties some days earlier than was at first intended he was able to retain a larger supply of provisions. Six sledges were taken on, and in spite of the difficulties of the way the party made excellent progress, and by reducing the rations they were able to continue the northward march to 86° 33′ 49″ in 64° 30′ E., which was attained on April 25. The journey at times was comparatively easy, the ice in places being smooth and covered with firm snow, but frequent pressure-ridges had to be surmounted and proved serious obstacles. In the latter part of the journey, when the temperature did not descend below zero Fahrenheit, lanes of water often opened with dangerous suddenness and caused great delay, while frequent gales and bad weather of every kind were encountered. The return journey, with rapidly dwindling provisions and diminished strength, was extremely laborious and the steady drift of the ice to the westward was a very serious difficulty, and, despite an increasing easterly component in the direction of march, the first land sighted was Harley and Neale Islands and Cape Mill, fifty miles west by south of Teplitz Bay. It was June 22 before the base was reached, and Captain Cagni had been absent 104 days, making (apart from the loss of the three men in the missing party) perhaps the most successful sledge journey ever accomplished in the Arctic regions, and certainly reaching the highest latitude.

The *Stella Polare*, after temporary repairs, was released from the ice with great difficulty, and only succeeded in getting away from Teplitz Bay on August 15, after which a good passage was made to Norway.

The results of the expedition are touched on slightly. Petermann Land and King Oscar Land, reported by Payer, have been shown not to exist in sight of the positions assigned to them. Cape Fligely (81° 51′) is proved to be the most northerly point of Franz Josef Land, and Cape Sherard Osborn does not belong to the same island, if it has any real existence. Doubt is thrown on the existence of the islands reported by Wellman north of Hvidtenland; but the maps of the Jackson expedition appear to have been found accurate so far as they could be tested. A year's meteorological and magnetic observations were obtained at Teplitz Bay, and gravity and tidal observations were also carried out. Prince Rudolf Island was found to consist entirely of basaltic rock. Animal life was not found very abundant, polar bears being the only common land mammals, and no new birds appear to have been discovered.

HAILSTORM ARTILLERY.

IN the absence of any recognised English equivalent for the expressive German term *Das Wetterschiessen*, I have thought it best in the heading of this article to avoid a literal translation of it lest it should give rise to misunderstanding. "Weather shooting" does not refer to any haphazard or empirical attempts to foretell the weather, but to a practice which has lately come to have great vogue in Styria, Italy and elsewhere of firing off charges of gunpowder to protect the vineyards against injury from hail. So popular indeed has the practice become in some districts that there is danger of the cost of the protection exceeding that of any damage likely to be caused by the hail.

The idea that the weather can be affected by the discharge of gunpowder is not a new one. There have been various traditions of rain falling after, and presumably in consequence of, the cannonade of a battle, and I have some recollection of an account in English newspapers of an American enterprise for terminating a drought by a sufficiency of gunpowder.

Weather shooting as now practised has, however, a more definite purpose than merely causing rain. Its object is to prevent the downpour of hail by shooting when thunder or hail clouds threaten. Even this form of the application of gunpowder to the management of the weather is by no means new. The *Meteorologische Zeitschrift* of March 1900 states, on the authority of Arago, that in the seventeenth century a fleet, anchored off Cartagena (South America), dispersed a daily afternoon thunderstorm by a daily bombardment; and Leonardo da Vinci is said to have asserted that damage by hail could be averted by mounting mortars on the hills from which the storm-clouds came and shooting at them. Quite early in the past century the matter was taken up in the neighbourhood of Macon. The recent development, which has spread very widely, is most conspicuously represented by the arrangements of Bürgermeister Stiger, of Windisch-Feistritz, in Styria, where they were originally introduced in 1896 in the form of a vine-dressers' volunteer artillery. Batteries of ten heavy mortars to take a charge of 120 grammes of powder, served by six men each, were placed at twelve separate stations within two square kilometres at a high level near Windisch-Feistritz. As soon as a downpour of hail threatened, the 120 mortars were fired "incessantly" until the danger was past. The second year thirty-three stations were at work, and the third fifty-six. It is reported that this energetic proceeding has completely protected the region from hail and has mitigated the damage from lightning; and as Bürgermeister Stiger apparently introduced the system as an alternative to covering the district with wire of close mesh, the damage must have been previously regarded as a serious matter. Other places have been less successful, and the Austrian Government and local authorities have taken steps to inquire into the effectiveness of the shooting. But the vineyard districts are not willing to wait for the report of the inquiry; they are satisfied that they only failed because they did not shoot early enough or often enough, and only desire to shoot more and oftener.

It is not quite clear how the effects of the shooting are manifested. In some cases it would appear that the shooting dispersed the clouds altogether, in others that it caused rain, sometimes heavy rain, sometimes a genial and welcome rainfall instead of the malignant pelt of the hail.

Dr. Pernter, of the Austrian Meteorological Department, was of the commission appointed to inquire into the matter, and in the September number of the *Meteorologische Zeitschrift* he gives a most interesting account of some experiments in connection with the inquiry. From that account it appears that there are three forms of apparatus employed, differing in size. A small cylindrical mortar with a large conical mouthpiece is the general form of the apparatus.

The conical portion of the smallest system (System Unger) is 2 metres long, that of the longest (System Suschnig) is 4 metres long; the former takes a charge of powder up to about 60 grammes, the latter up to about 250 grammes. Briefly, the latter is the most effective implement, and a charge of 180 grammes is the best suited for the purpose.

The effect of the shot is to produce, besides noise, a vortex ring of most impressive dimensions and energy. It would start with a loud hum and settle down to a whistle. When the gunpowder charge was most suitable, it would tear a thick paper screen to pieces at 100 metres distance from the mortar and pull the wooden framework of the screen apart and hurl the pieces about. Dr. Pernter, indeed, becomes quite eloquent in his description of the behaviour of these rings as astonishing physical experiments quite apart from any practical interest they may have as affecting the weather.

The position of the ring is recognisable by its whistle after it has become invisible, and its duration is estimated by the duration of the whistling. In the firing the rings are shot upwards, and it is assumed that the effect of the shooting depends upon them.

Dr. Pernter's experiments were directed mainly towards ascertaining the velocity and the length of the path of the rings, with the ultimate object of determining whether they could reach the levels of the lowest stratum of rain cloud. Determining the velocities from a very large number of experiments with charges of different weight, he obtained in the most favourable circumstances with the Suschnig apparatus an initial velocity of about 55 metres a second and a height of 400 metres as the extreme probable limit of the best shots. Thus the experiments seem to show that the rings would not reach the storm-clouds at the 1000-metre level, but as the local people were convinced from their own observations that the storm-clouds in the neighbourhood of St. Katherein (where the experiments took place) were to be found at 800 metres, and as the shooting-gear was fixed at elevations of some 500 metres, it seemed possible that the rings might just reach the clouds.

Such is the result of the investigation, with the addition that the smaller apparatus would not carry nearly so far, nor would the rings have anything like so much energy as those from the larger apparatus, whence it follows that if we wish to shoot the clouds effectively we must use the largest-sized mortars, taking 180 grammes of powder, and we should then be a little uncertain whether the ring would travel far enough.

Various theories have, of course, been suggested to account for the protection from hail alleged to be secured by this shooting. Supersaturated air from which the rain is liberated, a labile state of atmospheric equilibrium disturbed by the discharge, globules of overcooled water, still liquid below the freezing-point, which would form large hail-drops if they were allowed to coalesce but are solidified separately by the shock, and many other suggestions have been put forward as the state of things precedent to the hail shower, which is disarranged by the shooting. There seems, indeed, to be a disposition to see what curious conditions our present knowledge of the physics of the atmosphere can account for, and then wonder whether one of them might be the condition of things in a thunder cloud. Theory is very much at a disadvantage, because it is not at all clear what has to be explained, and it is, indeed, difficult to account for facts when we do not know what are the facts to be accounted for.

Dr. Hann has suggested, very properly, that the effect of shooting upon a winter fog should be ascertained. There appears to be some evidence that gun-firing clears the air of such a fog. But whether theory is to regard the noise or the smoke or the energy of the vortex ring as the cause of the effect, or whether, indeed, there is any effect to be explained, is not yet finally established. At the same time, no one is prepared to say that no effect is possible or is willing to lay claim to sufficient knowledge of the conditions of the atmosphere immediately preceding a hailstorm to venture any categorical opinion on the various theories. The subject was brought before the conference of meteorologists last year at Paris by several writers, and some additional information about it will doubtless appear in the report of that conference when it is published; in the meantime, the prominent meteorologists of the countries where there is a great popular demand for weather shooting, Styria, Hungary, Italy, Switzerland and France, are unanimous in the desire that the demand may lead to definite investigation of the nature of the processes taking place in thunderstorms, and especially in the formation of hail, which will lead to a real advance in our knowledge of these phenomena and will furnish a satisfactory basis for a theory of weather shooting. W. N. SHAW.

VIRIAMU JONES.

YET another gap in the front rank of science. But yesterday it was Fitzgerald, then Rowland, and now—Viriamu Jones is dead, the last, like the first, especially great in inspiring others.

Son of a working collier, a collier with rare gifts, the "poet-preacher" of Wales who thrilled with his silver tongue the gathered thousands and moved the multitude with his mighty eloquence, Viriamu inherited all those qualities which tend to greatness and came into daily contact with them in his own home. His very name indicated what was expected of him, for "Viriamu" was the name of the martyr missionary Williams, rendered as best it could be by the Polynesian tongue.

At the earliest permissible age of sixteen, Jones passed the London matriculation examination and won the scholarship in geology, the subject in which he took his degree with first-class honours three years later. Meanwhile he was gaining prizes, medals and scholarships at University College, London, and was elected Brackenbury scholar at Balliol College, Oxford. Going there at the age of twenty, he came under the direct influence of Jowett and commenced that personal friendship which influenced his whole life. After obtaining a first class in mathematical moderations in the final school of mathematics and in the final natural science school, he was elected principal and professor of mathematics and physics in the Firth College, Sheffield, when only twenty-five.

How he used to laugh because he always knew exactly what an examiner wanted; and what a true estimate did he form of the poverty of the examination system to test a man's real powers. How sympathetic was he when one was despondent at the unpractical character of the "intellectual miser," the student who spends his time acquiring and hoarding knowledge without giving the world a single new idea of his own. His views on education were of the broadest; to him the study of Greek and Latin, a problem in mathematics, the adjustment of a Whitworth measuring machine, were all equally living, and in the niceties of all three he showed the same absorbing interest.

No wonder, then, that when the first principal of the University College of South Wales had to be appointed the council chose the youngest of the thirty applicants —for that youngest was Jones in his twenty-seventh year. And no appointment ever made was better justified. The many speeches to his memory, the letters that have flowed in from every side, including one from the King, all prove how the work of the principal was appreciated, how the man was idolised.

He placed the University College system of Wales on a truly educational and democratic basis, and shaped the educational policy of his country by formulating the system of secondary education, which fills the gap between the primary schools and the colleges, and by the part he played in establishing a University for Wales.

The charm of his personality, his magic smile, the grace of his diction and his winning persuasiveness secured success where others could but court failure. Some 70,000*l.* he gathered together for the building of the new college, but a free site was still wanting, for this had been refused by the Corporation last summer, when Jones was too ill to be in England. Returning, however, in the autumn, he sought an interview, as a belated member of the deputation, charmed the Corporation into reversing their decision, and won for his college a site as a free gift. Well might Sir William Harcourt, when Chancellor of the Exchequer, jocularly say that Principal Jones was the cleverest beggar he had ever met with, and about the only one he could not get rid of without promising to give what was asked for.

Deep is the gratitude the college feels for its first principal; sincere is the praise Wales is reverently showering on the young first Vice-Chancellor of its University.

During the last few years I saw much of Viriamu Jones in connection with the construction of electrical standards, and I was always struck with surprise at the way in which one who found his greatest relaxation in studying the poetry of the most regular and attentive of his father's congregation—Robert Browning —discussed in detail why he thought the physical theories of the day too fanciful, and criticised the modern electrical measuring instruments for not being constructed on engineering lines.

His immediate ambition was to provide the National Physical Laboratory with electrical standards constructed like well-designed engineering machine tools rather than the ordinary physical laboratory apparatus, and it was towards such an end that his scientific work of recent years tended. A certain City company had promised him the funds for a far more perfect Lorenz apparatus than any yet made, and many were our talks about its details, how the coil and rotating disc were to be horizontal, and the non-magnetic driver a turbine, &c.

His first paper on this particular subject of electrical standards was published in 1888, and consisted of a determination of the coefficient of mutual induction of a circle and coaxial helix in connection with constructing the coil of a Lorenz apparatus by winding a *single* layer of wire in a screw thread cut on the surface of a large brass cylinder. For it seemed probable that with such a coil Lord Rayleigh's formula, which is a first approximation, would not give a result of sufficient accuracy, and Jones succeeded by a method of direct integration in obtaining a comparatively simple formula which gave the coefficient of mutual induction with greater accuracy, and enabled a single larger coil, the geometry of which can be better known than one of many convolutions, to be employed. In the following year he discussed the employment of Lissajous' figures for determining the rate of rotation of the disc of the Lorenz apparatus and of a Morse receiver for measuring the periodic time of the tuning-fork employed.

In 1890 he announced, at the meeting of the British Association at Leeds, that with the use of his specially constructed Lorenz apparatus the ohm was equal to the resistance of 106·307 centimetres of mercury one square millimetre in cross-section at 0° C., the complete account of the apparatus, its use, the mathematical calculations employed and the results obtained being published in the *Philosophical Transactions* of the Royal Society for 1891. Three years later he was elected a Fellow of that Society.

Appendix iii. of the 1893 Report of the British Association Committee on electrical standards consists of the results of his use of the Lorenz apparatus to measure directly the value of commercial low resistances of the order of 1/5000th of an ohm with an accuracy of one part in 12,000, as contrasted with the comparison of such resistances with a known standard in the ordinary ways. Appendix ii. of the 1894 Report deals with a determination of the ohm by measuring the absolute value of the resistances of a combination of four coils which had been compared with the standards of resistance in the Cavendish Laboratory; while in Appendix ii.

of the 1897 Report is a full description of the use of a Lorenz apparatus (constructed to Jones's designs for the McGill University) in determining the absolute values of the same four coils. From this it followed that a Board of Trade ohm equalled 1·00026 true ohms.

In the interim—viz. in 1896—he gave an account of the correction that would have to be made in consequence of a very slight ellipticity of his large brass coil, which he found to exist in 1894, and he showed that his 1900 value of 106·307 centimetres for the ohm would have to be increased to 106·319 on this account.

The formula developed by him in 1888 for the calculation of the mutual induction of a circle and a coaxial helix, although comparatively simple, in view of the accuracy obtained with its use, led, in reality, to a long laborious calculation when employed in practice. Consequently he spent some of the leisure of his voyage home from Montreal in 1897 in working out a simplification of the method previously described and a more general solution. And the account of this formed the substance of the paper he read before the Royal Society in November of that year.

Jones' ampere balance, briefly described in Appendix iii. of the 1898 British Association Report, was designed of a form which would readily lend itself to the use of a new formula (also developed in the preceding Royal Society paper) for the force between a uniform cylindrical current sheet and a coaxial helix, which could be readily expressed in elliptic integrals.

The liberality of the British Association, and of Sir Andrew Noble, will enable his standard ampere balance to be realised. The love of his friend will accomplish its completion.

Through Cardiff's hushed streets, contrasting strangely with their noisy traffic of other Saturdays, the long procession, last week, wended its way. Bright was the van with the mounted escort and the firemen's glittering helmets, sombre the rear with the girl students in their caps and gowns. By his father's side, high up on the hill overlooking Swansea Bay, we laid him—the man of high ideals, the man who had lived a long long life though dead at the age of forty-five. W. E. AYRTON.

It was right that one who did so much for the educational advancement of Wales should be given a public funeral. A memorial service was held at the Park Hall, Cardiff, on Saturday morning; the Bishop of Llandaff read the lessons, while the sermon was preached by the Rev. J. Williamson. After the service there was a procession to the Great Western Railway Station, and the gathering included representatives of important municipal and public bodies, the University of Wales, the University colleges of Wales and other educational authorities and institutions. A special train conveyed the body and the mourners to Swansea, where the interment took place, the Mayor of Swansea and the members of the Corporation, as well as representatives of local educational bodies, taking part in the mournful ceremony.

NOTES.

THE Royal Society announces that it is about to make the first award of the Mackinnon research studentship. The studentship is founded under a bequest to the Royal Society by the late Sir William Mackinnon, Director-General of the Medical Department of the Army, of the residue of his estate upon trust to be applied for the foundation and endowment of such prizes or scholarships for the special purpose of furthering natural and physical science, including geology and astronomy, and of furthering original research and investigation in pathology as the Society may think best and most conducive to the promotion of those sciences and of original discoveries therein. The committee appointed by the council of the Royal Society to advise upon the best mode of giving effect to the intentions of the testator recommended that the award should be in the nature of a studentship for the encouragement of research rather than a prize for the reward of past achievements, and that the studentship should be devoted to the maintenance of a student engaged in such researches as were indicated by the testator. The studentship will be awarded this year in one of the biological sciences, including physiology and anatomy, pathology, botany, palæontology and zoology; it will be awarded for one year, but will be renewable for a second year. The studentship is at present of the annual value of 150*l*., but the awards may be multiplied in future, upon the determination of certain outstanding charges upon the property. Applications must be received not later than June 26 by the assistant secretary of the Royal Society, from whom further particulars may be obtained.

THE gold medal presented biennially by the Pharmaceutical Society in memory of Daniel Hanbury, for high excellence in the prosecution or promotion of research in connection with the chemistry and natural history of drugs, has this year been awarded to Dr. George Watt, reporter on economic products to the Government of India. Dr. Watt, says the *Pharmaceutical Journal*, was born at Old Meldrum, Aberdeenshire, on April 24, 1851, and was educated at the Grammar School, King's College, and Marischal College, Aberdeen, subsequently graduating as M.B., with first-class honours, in the University of Glasgow. He became assistant professor of botany at Aberdeen in 1871, and professor of botany at Calcutta University in 1873. His best-known work is the "Dictionary of the Economic Products of India," but he is also editor of the *Agricultural Ledger*, and of the report of the Central Indigenous Drugs Committee of India for 1900, as well as the author of reports on the pests and blights of the tea plant, on rhea and China grass, on lac and the lac industries of India, and on a plague in the betti-nut palms of India. He has also published a "Flora of Chamba," a monograph on the Primulaceæ, and other scientific and technical works. Dr. Watt is still engaged in clearing up the difficulties that surround the botanical sources of aconite roots of Indian commerce, and has only recently furnished material for the investigation of kino.

THE conditions which will control the administration of Mr. Carnegie's munificent gift to Scottish Universities have now been published, and they remove the difficulties which presented themselves when the announcement of the donation was made, but no particulars were available as to its allocation. The annual income from the trust is estimated at 104,000*l*., and it is to be administered by an executive committee of nine members, the first committee being constituted as follows:—The Earl of Elgin, who is to act as chairman, Lord Balfour of Burleigh, Lord Kinnear, Sir Henry E. Roscoe, Mr. Shaw, the Lord Provost of Edinburgh, the Lord Provost of Glasgow. Two remaining members are to be two of four trustees nominated by the University Courts, the members for Edinburgh and Aberdeen acting during the first two years, and the members for Glasgow and St. Andrews acting during the second two years. One-half of the net annual income is to be applied towards the improvement and expansion of the Universities of Scotland in the faculties of science and medicine, also for improving and extending the opportunities for scientific study and research, and for increasing the facilities for acquiring a knowledge of history, economics, English literature and modern languages, and such other subjects cognate to a technical or commercial education as can be brought within the scope of the University curriculum. The other half of the income, or such part thereof as in each year may be found requisite, is to be devoted to the payment of the whole or part of the ordinary class fees exigible by the Universities from students of Scottish birth or extraction and of sixteen years of age and upwards, or scholars who have given two years' attendance after the age of fourteen years at State-aided schools in Scotland, or at such other schools and institutions in Scotland as are under the inspection of the Scotch Education Department. Any surplus remaining in any year from the income applicable to this head of expenditure is to be applied to the first head of expenditure. In the case of schools or institutions in Scotland established to provide technical or commercial education, the committee may recognise classes which, though outside the present range of the University curriculum, can be accepted as doing work of a University level, and may allow them and the students thereof to participate under both heads of the trust deed. The benefit of the trust is to be available to students of both sexes. The trustees are to have full power, by a majority of two-thirds of their number, to modify the conditions under which the funds may be applied so as to secure that these shall always be applied in the manner best adapted to meet the purposes of the donor as is expressed in the constitution, according to the changed conditions of the time.

THE new Pathological Institute at the London Hospital will be formally opened by Sir Henry Roscoe, vice-chancellor of the University of London, on Wednesday, July 10, at 3 o'clock.

THE American Chemical Society has elected the following honorary members:—Prof. W. Ramsay, Sir Henry E. Roscoe, Prof. E. Fischer, Berlin, Prof. A. Baeyer, Munich, and Prof. G. Lunge, Zurich.

THE gentlemen selected by the council of the Royal Society for admission as Fellows this year were elected at the meeting held last week. The qualifications of the new Fellows were given in NATURE of May 9 (p. 36).

THE sixty-ninth annual meeting of the British Medical Association will be held at Cheltenham on July 30—August 2. The president-elect is Dr. G. B. Ferguson. An address in medicine will be delivered by Dr. J. F. Goodhart and an address in surgery by Sir William Thomson. The scientific business of the meeting will be conducted in thirteen sections.

THE establishment of a Ministry of Commerce, under a minister of business experience, is being actively urged by the *Daily Express*. A provisional committee has been formed, consisting of a large number of Members of Parliament, civic authorities, presidents of Chambers of Commerce, and heads of important business firms. It is proposed to hold a public meeting in London at an early date, with the object of forming an association and generally to take practical steps in the organisation of the movement.

THE Paris correspondent of the *Times* announces that M. Th. Ribot, professor of experimental psychology at the Collége de France, the founder of the *Revue Philosophique* and the inspirer of an entire generation of students and professor of the new psychology, not only in France but all over the world, will retire on a pension, at his own request, at the beginning of November.

WE are informed that, in the unavoidable absence of the president of the Institution of Electrical Engineers, Mr. Alexander Siemens (past president) will, at the unanimous request of the council, assume the leadership of the Institution party throughout the visit to Germany. Members are reminded that their applications for tickets should be forwarded before Saturday next, June 15.

ACCORDING to the latest returns the population of Paris increased during the last five years by 6·98 per cent. At the last census, which was taken at the end of March 1896, the inhabitants numbered 2,536,834; but at the present time the total is 2,714,068.

AT the annual meeting of the Akademie der Wissenschaften, of Vienna, on June 1, it was announced that Prof. Eduard Suess had been unanimously re-elected president for a further period of three years. Thereupon the Professor delivered his presidential address, which contained, amongst other scientific statements, some valuable references concerning the life and works of the late Prof. Max Müller, of Oxford, who for many years was honorary member of the Akademie. Prof. Berthelot, of Paris, was nominated honorary member, and the following gentlemen were elected as foreign corresponding members:—Profs. Schlegel (Leyden), Oppert (Paris), Linde (Munich), Retzius (Stockholm), Kowalesky (St. Petersburg).

BY the courtesy of the editor of the *Chemist and Druggist* we are able to give an illustration of the monument to Pasteur, shortly to be erected at Dôle, where he was born. The statue,

Monument to Pasteur, to be erected at Dôle.

the sculptor of which is M. Antonin Carles, is in bronze, and stands on a pedestal eight metres high. The figures at the base of the monument represent Humanity bringing two children to Pasteur, while Science offers him a palm.

THE *Electrician* announces that the system of etheric signalling devised by Sir William Preece has been successfully installed for the purpose of placing Rathlin Island in telegraphic communication with Ballycastle. The distance over which the signals are transmitted is about ten miles, as the waves go, and the lengths of inductive wire employed on each side are one and six miles respectively, the shorter length being on the island. The telephone was used as the receiver, with Morse signals transmitted by means of a "buzzer"—a more rapid if less sensitive arrangement than the Marconi coherer.

REFERRING to the death of the ethnologist Dr. Arthur Hazelius, on May 27, in his sixty-eighth year, the *Athenaeum* says he was the founder of the Ethnographical Nordische Museum and of the unique and interesting Skansen, the open-air museum in the Zoological Garden of Stockholm, the result of nearly thirty years of labour, where the national life of old

Sweden is represented in vivid fashion, not merely by means of buildings, but also by the festivals and music of earlier times. Dr. Hazelius's son has, it is stated, been elected to succeed him as director of the Nordische Museum.

THE death is announced of Mr. William Walton at Little Shelford, near Cambridge. He was born in 1813 and graduated as a member of Trinity College in the mathematical tripos of 1836, being eighth wrangler. After taking his degree he remained at Cambridge and became a successful private tutor and lecturer in mathematics. He published a considerable number of mathematical treatises which for many years were used as text-books by students. His chief works were a treatise in illustration of the principles of theoretical mechanics and a volume on the differential calculus.

AN International Fire Prevention Congress met at Berlin last week, under the presidency of Count Komarowsky. The first resolution, which was unanimously carried, was proposed by Mr. Edwin O. Sachs, and was in the following terms: (1) That the serious investigation of the fire resistance of materials and systems of construction should be supported both by the Government and local authorities, as well as by those technical societies to whose members the results of such investigations are important in the practice of their professions. (2) In view of the fact that identical materials and systems of construction are frequently employed in different countries, an effort should be made to standardise the results obtained from fire tests in such a manner that the investigations made in different countries should be compared in a practical manner with due regard to units of measurement and temperature.

WE regret to see the announcement in the *Times* of the death of Prof. Bleicher, director of the school of pharmacy in the University of Nancy, and formerly professor of natural history at the same school. He was shot by a pharmacist from whom a sample of cinchona had been seized for analysis at the school. This crime has deprived France of one of the scholars who have done most to reveal to the world the geological interest of the frontier provinces of France. Prof. Bleicher's "Les Vosges, Le Sol, et Ses Habitants" is a classical treatise which every traveller in Alsace-Lorraine should always carry with him. Every year Prof. Bleicher spent his holidays on one or other of the slopes of the Vosges, studying the stratifications, the rocks, the glacial marks, all the features, in a word, of this interesting region, upon which he had published a large number of memoirs. He had begun life as Médecin-Major in the French African army, but left his work there in 1877 to become professor at Nancy, where he was very popular, often conducting students' scientific expeditions.

THE scientific study of plant associations and conditions of growth of crops was urged by Mr. R. Hedger Wallace in a lecture delivered at the museum of the Royal Botanic Society on Friday last, Sir George Kekewich, K.C.B., being in the chair. He remarked that commercial crop cultivation as a subject correlated the practical details taught by economic geography and botany. The mapping of plant associations would be of service, because wherever a man wishes to cultivate the ground a study of its actual flora is the most trustworthy guide to the possibilities of success or failure of new species. To the agriculturist and horticulturist the characteristics of plant areas are better guides than those of climate alone, because in plant distribution the influence of soil and drainage is correlated with that of climate. What are needed, the lecturer stated, are maps showing natural plant areas, cultivated crop areas and zones of cultivation, distinguished by definite colours like a geological map. With respect to plant distribution and zones of cultivation, attention was directed to the work that has been done in Germany, especially by Profs. Oscar Drude and Engelbrecht. The botanist who studies the distribution of plants usually eliminates all consideration of the plants that are cultivated by man as vitiating his inquiry. Engelbrecht, on the other hand, deals entirely with the distribution of cultivated plants, though his survey is restricted to agricultural and horticultural produce grown outside the tropics. To study the commercial crop cultivation of a country the geographical conditions should be noted. Land forms, that is, the relief of the land, have a powerful influence, indirectly as well as directly, on plants, animals and human beings. An endeavour should therefore be made to gain some idea of what might be termed the climatic control of land forms, and the influence of land forms on natural flora and cultivated crops.

WITH reference to the inquiry of a correspondent as to the appearance of the Hoopoe on Lundy Island (p. 132), Mr. W. H. Graham writes from Fowey, Cornwall, "I dare say your correspondent would be interested to know that I saw a Hoopoe here in 1900, and one has been seen here this year; both were seen in the early spring, March, I think. Possibly those on Lundy Island have crossed from Cornwall."

THE invention of the Poulsen telegraphone, a full description of which in its latest form we hope shortly to publish, seems to have stimulated efforts to replace the wax cylinder phonograph by some more satisfactory arrangement. Descriptions of two new phonographs have quite recently been published—one the invention of Prof. Nernst and R. von Lieben, and the other invented by E. Ruhmer. A full account of Prof. Nernst's arrangement appears in the *Electrician* for June 7. The principle of which he makes use is the alteration of polarisation capacity and surface resistance of a metal used as an electrode in an electrolytic bath. A copper disc about 3 mm. thick is rotated at a fairly high speed, whilst there presses against its edge a thin wedge of wood soaked in an electrolyte. The secondary currents from the induction coil of a microphone transmitter are caused to pass through this contact and leave a record on the edge of the disc on account of the varying amount of chemical change produced. A telephone receiver is then substituted for the microphone, a battery being included in the circuit, and on again rotating the disc a reproduction of the sound is obtained. The best results seem to have been given by a solution of potassium zincate, using the edge of the copper disc as kathode, the wedge standing in a bath of the solution into which a zinc anode dips. With this, it is stated, the sounds can be reproduced clearly and distinctly two or three hundred times. The record can be cleaned off with fine emery paper.

RUHMER'S phonograph is based on an entirely different principle, thus making the third new phonographic method worked out in the past few months. The information at present at hand is, however, very scanty, so that we cannot do more than state the general claims of the inventor. Herr Ruhmer photographs, on a moving film, a sensitive flame which is being affected by sound vibrations, and thus obtains on the film a band of varying intensity; light is then projected through this band on to a selenium cell which is included in circuit with a battery and telephone. The variations in intensity as the film is passed before the source of light cause variations in current in the telephone circuit which reproduce the original sounds. The reproduction, it is said, is clearer than in the Poulsen telegraphone, and as an additional advantage multiplication of the records can be carried out photographically to any desired extent.

DURING the last few years the Danish Meteorological Institute has issued a very useful volume entitled "Nautical-Meteorological Annual." That for the year 1900 has just appeared and contains a summary of the state of the ice in the Arctic seas for each of the months March to August, with maps. Generally speaking, there were considerable masses of ice during the season 1900 in the north-west of Barents Sea, around Spitzbergen and in the Kara Sea, less than usual between Franz Joseph Land and Nova Zembla and on the east coast of Greenland, while in Baffin Bay and near Labrador the conditions were particularly favourable. The volume also contains tables showing the diurnal amplitude of the air at the various Danish light-vessels, and the surface temperature of the sea in the northern Atlantic Ocean and Davis Strait. The greater part of the work is taken up by carefully compiled tables of general meteorological observations, taken every four hours by the light-keepers, together with monthly means. These form a valuable contribution to the meteorological statistics of the northern parts of Europe.

M. D. KORDA announces in the *Bulletin* of the French Physical Society that in a fraction of a minute he has succeeded in crystallising ferrosilicium in the bottom of a crucible by cooling with water. The form of the crystals varies with the proportion of silicon—long needles for 10 to 100 of silicon (Fe_2Si), tetrahedra of 1 to 10 mm. length of side for 22 to 23 per cent. of silicon (FeSi), and laminæ of micaceous character for 50 per cent. of silicon ($FeSi_2$). Crystals of ferromanganese or ferrochromium can be similarly formed.

DR. EMILIO ODDONE describes, in the *Rendiconto* of the Lombardy Institution, experiments conducted for the purpose of determining the mean coefficient of transparency of the air over distances considerably greater than those previously experimented on, and he gives examples of the application of this method to distances of 45, 85 and 135 kilometres. The coefficients are fairly high, increasing with the distance, and the ultimate values are only slightly less than those corresponding to vertical vision. From this property, Dr. Oddone thinks it possible to calculate approximately the thickness of the atmosphere in the direction of the zenith.

THE *Archives* of the Röntgen Ray contains a short programme of the Röntgen Exhibition to be held in Hamburg in connection with the seventy-third meeting of the Deutscher Naturforscher und Aerzte. The scientific part will be in the hands of Dr. Albers-Schönberg, Dr. Walter and Dr. Hahn, while the literary part will be taken by Messrs. Lucas Gräfe and Sillem. The physical section will include induction coils and contact breakers, portable apparatus, tubes, fluorescent screens, operating tables, stereoscopes and other accessories, power for working the coils, &c., being obtainable at 220 volts continuous and 120 volts alternating current. The medical section will exhibit the latest achievements in radiography and the therapeutic uses of Röntgen rays. In addition with the above it is mentioned that at a recent sitting of the Prussian Kultus Ministerium the Universities received a grant of 1000*l.* for additions to the Röntgen ray departments.

UNDER the title "A New Era in Interior Lighting," Mr. Charles L. Norton writes in the *Technology Quarterly* advocating the use of ribbed, corrugated and prismatic glass windows for diffusing light in the interior of rooms and offices. The only comment we can make is that as modern civilisation compels men to work in dingy offices and factories it has been necessary for modern civilisation to devise some means of lessening their dinginess, then "adaptation to environment" will come in and give us a civilised race which actually prefers this kind of illumination to that of the good old plate glass window. Of this tendency Mr. Norton himself affords an instance when he expresses the view that it is to be *regretted*, but it is certainly true, that strong objection is often made to the "shut in" feeling which some people experience in rooms glazed wholly with diffusing glass. He also considers it one of the uses of the diffusing window that it allows of the closer approach to one another of tall buildings, with a resulting economy of land—and, we should say, an aggravation of the unnatural conditions under which human life maintains its unlovely struggle for existence in densely populated centres.

IT is interesting to notice how the naval architect is becoming more and more dependent on a knowledge of applied mathematics and mathematical physics for the solution of the problems involved in perfecting the construction of steamships. It is only recently that the balancing of marine engines has received serious attention, and this problem has brought the principles of rigid dynamics as well as Fourier's series under the notice of the shipbuilder. But when the parts of an engine have been balanced on the hypothesis that they are perfectly rigid there still remain the effects of their elasticity to be taken into account. Mr. J. H. MacAlpine has recently communicated to the *Journal* of the American Society of Naval Engineers a monograph of 288 pages on "Inertia Stresses of Elastic Gears." The investigation seems to have been suggested, in the first instance, by the defective working of certain forms of valve gear. While Mr. MacAlpine hardly thinks that the elaborate processes of calculation which he gives can be frequently repeated in the ordinary course of designing, they might, at least partly, be resorted to with advantage and with but little labour, in cases where the effect of elasticity seems doubtful. Their application would have saved many expensive breakdowns in the past, and if applied to such cases as the *Newark*, where serious trouble has arisen, would gradually accumulate a store of valuable data which could not fail to be useful.

IF we may judge by the Report of the Marlborough College Natural History Society for 1900, the issue of the Victoria series of County Histories is having a good effect on institutions of this nature in calling attention to the incompleteness of their records of local faunas. In this particular instance, the local lists of the popular groups of Hymenoptera, Lepidoptera and Coleoptera were found to be well worked up, but those of other groups of insects had been much neglected. The editor also calls attention to the advisability of schoolboys confining their attention to a single section of zoology; otherwise, with the multitude of other studies and occupations, any real progress is impossible.

WE regret to learn, from a communication by Mr. A. J. North to the Records of the Australian Museum for 1901, that the destruction of native birds in New South Wales is attaining alarming proportions. After referring to a recent newspaper article containing an account of the slaughter of about 250 lyre-birds by one man during a single season, the author dwells on the injury done to bird-life in Australia by the growth of the great cities and their suburbs and the consequent clearance of timber and coppices. In Sydney the diminution in the number of indigenous birds owing to this cause is bad enough, but it is nothing to what has occurred in Melbourne, which is virtually denuded of trees for miles around. But this is by no means all, for the introduction of foreign mammals has played havoc with many kinds of native birds. Now that the rabbits have been eradicated in many districts the cats introduced to prey upon them have turned their attention to the birds; and the introduced foxes, in addition to robbing hen-yards, destroy hosts of indigenous birds. Neither can the sparrow and the starling be exonerated from blame in the matter. Mr. North urges the necessity of the duty of bird-protection being taught in the schools, as in the United States.

THE significance of spiral swimming—that is to say revolution on their own longer axis—by many of the lower organisms, such as the ciliate and flagellate infusorians and volvox, is discussed by Dr. H. S. Jennings in the May issue of the *American Naturalist.*

The function is considered to be of considerable importance. It has been found that the same side of the organism is always directed towards the outer side of the spiral. In the case of spherical organisms like volvox the spiral movement probably serves merely to correct any accidental deviations from a straight course; but without this device many creatures would be quite unable to steer straight, and many of them would merely describe circles without making any forward progress at all. "The simple device of revolving in the axis of progression is surprisingly effective, in that it compensates with absolute precision for any tendency, or combination of tendencies, to deviate from a straight course in any direction."

We have received three specimen numbers of a popular Danish illustrated weekly magazine called *Frem* (Forwards), and devoted to ancient and modern history, archæology, literature and science. The outer portions of the paper are in quarto, but the inner portion, when cut up, consists of an octavo sheet, containing four pages each of various independent works. The parts before us, published in September and October, 1900, include parts of a novel; a translation of Shakespeare's "Henry IV."; a work on ancient history by Johan Ottosen, with illustrations of buildings, a cross, &c.; and a work by Levyson on the human body, with numerous text illustrations, and coloured diagrams of the organs of the upper part of the body and of the heart. The quarto contents of the parts are equally varied, and among them we notice articles and illustrations relating to the tortoises of the Orinoco, a Khirghis mother and children, edible and poisonous fungi, runes, old buildings, gout, the Moloch lizard, the Franco-German war, China, and the Transvaal, &c. It is one of the most miscellaneous publications which have come under our notice, in some respects resembling the old *Penny Magazine* of sixty years ago. *Apropos* of Shakespeare, we may mention that the plays are being translated into Finnish; and seventeen have already been published by the Finnish Literary Society at Helsingfors.

Contorted Beds at Jangye-Ryn, Gunwalloe.

The *Journal of Botany* for June gives the more interesting notes contained in the Botanical Exchange Club Report for 1899, which is now edited by the Rev. W. R. Linton.

Mr. F. N. Williams has issued a specimen of a "Prodromus Floræ Britannicæ," in which an attempt is made to epitomise the distinguishing characters of all British species and subspecies of plants, the descriptions being given in Latin, "the nominative absolute style with separate sentences."

The Royal Geological Society of Cornwall has lately issued its eighty-seventh Annual Report, together with the papers read during the session 1889–1890 (*Transactions*, vol. xii. part 6). Mr. J. B. Hill, who is engaged on the Geological Survey, has brought the experience which he gained in Argyllshire to bear on the slaty rocks of Cornwall. He finds the structures there to be identical with those of crystalline schists, but the mineralisation is wanting. In the Falmouth district the strata have been thrown into a series of isoclinal folds accompanied by small faults, and further minor structures have been set up until the mass has become full of minute folds and thrusts. These disturbances have in some cases caused, not only severing and brecciation of the bands, but also the rounding of fragments so as to produce "crush-conglomerates." The author remarks that had the rocks been subjected to these stresses at a greater depth and below the zone of fracture, where they would not have been so free to move, they would have been converted into true schists. Mr. Howard Fox gives a brief description of the remarkable contorted beds of Gunwalloe, in the Lizard district near Helston, together with an excellent photographic plate (which we reproduce by permission of the Society). The thick pale bands are grits, the thin dark bands are much squeezed shales, and there are numerous quartz and calcite veins. The beds appear to belong to the same group as the Ordovician cherts of Mullion Island. In an article on the sequence of the Lizard Rocks, Mr. Harford J. Lowe brings forward evidence to show that the granulitic series is later than, and instrusive in, the serpentine.

We have received the first number of a new botanical journal, to be issued at irregular intervals, *Biltmore Botanical Studies*, embracing papers by the director and associates of the Biltmore Herbarium, North Carolina. The present number is occupied by five papers on descriptive phanerogamic botany.

In a new edition of "Modern Cremation," which has just been published by Messrs. Smith, Elder and Co., Sir Henry

Thompson adds some important matter to the previous edition, and brings the history of the practice of modern cremation up to the present time. The case for cremation or some method of disposing of the dead other than burial is given much support by the evidence described in this book. The practical details given in an Appendix will be of service to people seeking information upon the subject.

MESSRS. DULAU AND CO. have sent us a copy of their various catalogues of zoological and palæontological books and pamphlets issued between 1896 and 1901. These, which are arranged in subjects, have been bound together into one volume, which will be found of considerable use to the working naturalist as a guide to much of the literature of any subject on which he may be engaged.

A NEW edition, revised and enlarged, of Prof. W. C. Unwin's "Elements of Machine Design" (Part 1) has just been published by Messrs. Longmans, Green and Co. The plan and general arrangement of the book remain the same as the original, published many years ago, but about a hundred pages have been added and numerous alterations have been made.

A NEW edition of "Telephone Lines and their Properties," by Prof. W. J. Hopkins, has been published by Messrs. Longmans, Green and Co. Among the additions are an account of the latest developments in the design of long lines, a chapter on "composite" working and wireless telephony, an abstract of Dr. Pupin's paper on telephony over cables and long-distance air lines, and a paper on inductive disturbances in telephone circuits.

RECENT numbers of American geographical journals contain much information about Alaska. In the May issue of the *National Geographic Magazine* Mr. Henry Gannett publishes an article on the general geography of Alaska. The second number of *Mazama* is devoted almost entirely to Alaska; it includes an account of the Harriman Alaska Expedition and a reproduction and explanation of an Indian map from the Chilkaht to the Yukon. *Mazama* also contains a paper on the flora of Mount Rainier, by Prof. C. V. Piper.

THE value of "The Statesman's Year Book" (Macmillan and Co., Ltd.) can only be rightly appreciated by those who keep the annual at hand for ready reference. The edition for 1901 has now appeared, and Dr. Scott Keltie and his colleague, Mr. Renwick, are again to be congratulated upon its publication. The work is an epitome of political geography, containing the essential particulars concerning the constitution, communications and commerce of every country in the world. The changes of the past year have necessitated the revision of several parts of the book. The Transvaal and the Orange Free State are now included in the section on the British Empire, and the Australian Commonwealth is described. The results of the censuses taken during last year and the early part of this are also given. There are five maps, the first giving a comparative view of geographical knowledge and political divisions in 1800 and 1900, and the second showing the political partition of Europe in the same years. The other maps represent railways, navigable waters and steamship routes in North America, South America and Australia. The volume now extends to 1320 pages, and ought not to be much further increased in size or it will lose its present handy character.

THE additions to the Zoological Society's Gardens during the past week include a Chacma Baboon (*Cynocephalus porcarius*, ♂) from South Africa, presented by Mr. Geo. Blay; a Rhesus Monkey (*Macacus rhesus*) from India, presented by the Hon. Mrs. Morrison; a Bonnet Monkey (*Macacus sinicus*) from India, presented by Colonel B. McCalmont; a Pin-tailed Whydah Bird (*Vidua principalis*) from West Africa, presented by the Hon. Mrs. Parker; two Ocellated Sand Skinks (*Chalcides ocellatus*), South European, presented by Mr. W. H. St. Quintin; two Common Vipers (*Vipera berus*), British, presented respectively by Mr. Gerald Leighton and Mr. John Wright; a White-collared Mangabey (*Cercocebus collaris*), two Yellow Baboons (*Cynocephalus babouin*) from West Africa, a Yellowish Capuchin (*Cebus flavescens*), a Brazilian Tortoise (*Testudo tabulata*) from South America, a Silky Marmoset (*Midas chrysoleucos*) from Rio Madeira, Brazil; two Pinche Monkeys (*Midas oedipus*) from Colombia, a Three-banded Douroucouli (*Nyctipithecus trivigatus*) from Guiana, three Serrated Terrapins (*Chrysemys scripta*) from North America, two Black Tortoises (*Testudo nigra*) from the Galapagos, a Black Iguana (*Metopoceros cornutus*) from the West Indies, a Common Chameleon (*Chamaeleon vulgaris*), a Basilisk Chameleon (*Chamaeleon basiliscus*, from North Africa, a Blue-tongued Cyclodus (*Tiliqua scincoides*), thirteen Black and Yellow Cyclodus (*Tiliqua nigro-luteus*) from Australia, four Green Lizards (*Lacerta viridis*), three Dark Green Snakes (*Zamenis gemonensis*), three Tessellated Snakes (*Tropidonotus tessellatus*), two Æsculapian Snakes (*Coluber longissimus*), a Four-lined Snake (*Coluber quatuorlineatus*), European; a Chained Snake (*Coluber catenifer*) from California, deposited; a Red Deer (*Cervus elaphus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

TWO NEW VARIABLE STARS.—Prof. W. Ceraski announces in the *Astronomische Nachrichten* (Bd. 155, No. 3718) the discovery of two new variables at the Moscow Observatory. The measures were obtained from photographs.

72, 1901 (Lyræ).

R.A. h. m. s.		Decl. ° ′ ″		
19 7 37·01	...	+33 10 12·6	...	1855·0
19 9 17·62	...	+33 14 38·1	...	1900·0

The brightness varies from the 10th to 12th magnitude, in a period of from 0·27–0·81 of a year. At present it is about the 11th magnitude, and is increasing.

73, 1901 (Scuti).

R.A. h. m. s.		Decl. ° ′		
18 46 19·7	...	−12 46·9	...	1855·0

This variable is of the Algol type; normal magnitude about 9·0. Its period is about 22·9 hours, and its brightness varies from 9·1 to 9·6 in five hours. There appears to be evidence of two principal minima separated by a secondary one.

UNIFORM TRANSMISSION OF ASTRONOMICAL TELEGRAMS.—Prof. H. Kreutz, of the Central Astronomical Telegraph Bureau at Kiel, has issued a circular in several languages suggesting instructions for securing the adoption of a uniform system for the transmission of astronomical telegrams from the various observatories of Europe to the central bureau for subsequent general circulation.

The code suggested is very similar to that already in use for the telegrams which have been sent out from Kiel for several years past. A definite order is agreed on for the descriptive items of object, discoverer or observer, time, position, magnitude, motions and remarks, with a terminal number to control the accuracy of the numerical part of the message. In the circular issued examples of various possible forms of messages are given, both at length and in code, dealing with the discovery of comets or planets, new stars, orbits of comets, ephemerides, &c., perusal of which will easily make the scheme clear.

PHOTOGRAPHY OF CORONA.—In a reprint from a paper read before the Photographic Society of Philadelphia on March 13, 1900, Mr. H. W. Du Bois draws attention to the possibilities of the method, outlined by Prof. Nipher, of developing a positive from a plate which has received great over exposure, in connection with the problem of the daylight observation of the solar corona.

ELECTRO-MAGNETS.

IN this article it will be shown what a great advantage results from constructing electro-magnets on scientific principles, instead of making them according to everyday notions, and to give an idea which is the best form to adopt for producing very strong magnetic fields.

To understand the matter we must first consider the magnetic circuit, which is very analogous with the simple electric circuit. Just as when we have an electric current flowing in a copper rod, say, we know that the current is flowing round a complete circuit of which the rod forms only a part, so in the case of an iron rod magnetised by a current flowing round it, we consider that magnetism flows round a complete circuit of which the iron rod forms only a part. Fig. 1 is an ordinary bar electro-magnet; and in Fig. 2 B represents a cell and C A a copper rod the ends of which are joined by a great many thin wires of high resistance.

Now the flow of current in Fig. 2 is exactly analogous with the flow of magnetism in Fig. 1. The cell replaces the coil of

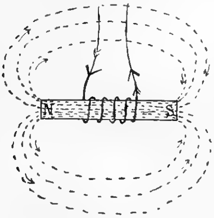

FIG. 1.

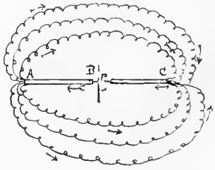

FIG. 2.

wire on the magnet, for whereas the cell sends the current in Fig. 2, the current flowing through the coil sends the magnetism in Fig. 1 through the iron rod, corresponding with the copper rod, and to complete the magnetic circuit the magnetism passes through the air in paths shown by the dotted lines, Fig. 1, back to the south pole of the magnet; so that the magnetic circuit in this case is formed partly of iron and partly of air.

The current flowing in the coils of wire on the magnet produces what is called a "magnetomotive force," which is proportional to the current and to the number of turns of wire; and a certain fraction of this quantity is used to send the magnetism through the iron rod and the remainder to send it through the air, or, in other words, every little piece of the magnetic circuit requires a certain magnetomotive force to drive the magnetism through it, and the sum of all these, taken all round the circuit, is the whole magnetomotive force due to the current in the coils; just as a certain part of the electromotive force of the cell is used to send the current through the copper rod and the remainder to send it through the thin wires forming the rest of the circuit. In fact, even the law governing the production of magnetism in a magnetic circuit is very similar to Ohm's law for the flow of current in an electric circuit, namely, that the amount of magnetism produced is equal to the magnetomotive force producing the magnetism, divided by the magnetic resistance, or "reluctance," as it is called, of the entire magnetic circuit. Hence, if the amount of magnetism is to be as large as possible it is just as important that the reluctance of the entire circuit should be small as it is that the current and number of turns of wire be large.

Now the reluctance of any little bit of a magnetic circuit, say from S to N, Fig. 1, for example, is proportional to the length of the piece, inversely proportional to its cross section, and also inversely proportional to the magnetic conductivity, called permeability, of the material. Therefore, to make the reluctance of our circuit small, we have to make: (1) its length small, (2) its cross section large, (3) and make it of a material whose permeability is as large as possible.

But the important thing is that the reluctance of the whole of the magnetic circuit must be small, not only of any particular part of it. For example, in Fig. 1, making the diameter of the iron bar large simply makes the reluctance of the circuit from S to N small, while the reluctance of the rest of the circuit, from N through the air to S is still very large, because the permeability of air is very small compared with that of iron. But if the bar is bent round into a ring, Fig. 3, then the reluctance of the whole circuit is reduced, and consequently a larger amount of magnetism will be produced in the bar for the same current flowing round it, and the density of the flow—that is, the strength of the magnetic field in the air space—will be very much increased.

There seems to be a popular idea that if a magnet is to produce as strong a field as possible it must be wound with an enormous number of turns of wire and a very large current sent round the coils, and that nothing else is of the least consequence. The following is a description of a large electro-magnet, made only about three years ago, which well illustrates this. It formed part of an electrical instrument intended to be used in connection with submarine telegraphy, the sole function of the magnet being to produce a very strong magnetic field. This result was certainly not obtained because it was not properly designed.

The magnet consists of two iron cores, 6 centimetres in diameter, each wound with about 1500 turns of wire, making the outside diameter more than 16 centimetres. To illustrate the

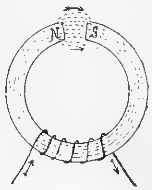

FIG. 3.

uselessness of this great amount of wire compared with the cross section of the iron, it has been found by experiment that if only one-third of the ordinary current is sent round the coils the strength of the magnetic field is thereby reduced only 15 per cent. If therefore the magnet had been wound with one-third the number of turns the cost of materials would have been about halved, and the power used to excite it only one-third, and even a less reduction than 15 per cent. in the strength of the field would have resulted.

The cross section of the piece of iron joining the two cores, *i.e.* "the yoke," is less than half that of the cores, and consequently the density of the flow of magnetism in the yoke is very large, and this means that the yoke will offer a great resistance to the magnetism for two reasons: (1) because the area is small, (2) Because the density being so large the permeability will be very small, for the magnetic conductivity gets rapidly less the greater the density; in fact, in this case the reluctance is so large that when the magnet is excited with its ordinary working current it produces a field of only 7900 C.G.S. units, and it can be calculated that the magnetomotive force used to send the magnetism through the yoke is then more than four times that required for the air gap, whereas in a properly designed magnet nearly all the magnetomotive force is used to send the magnetism through air gap and pole pieces. Doing what has been done here is exactly analogous with trying to send the strongest current that you can through an electrical apparatus by connecting to it the most powerful battery obtainable with two very long thin high-resistance wires. Analogy, therefore, shows us that the cross section of the yoke should have been made at least equal to that of the cores.

In order to see what sort of saving might have been effected, I have designed a magnet (Fig. 4) to produce the same effect as this one.

It consists of a cast steel ring, rectangular in section, the wire being wound on ten bobbins made of thin wrought iron, and not straight on the ring, for convenience in winding.

The design is made by starting with the assumption that a magnetic field exists of the strength desired in an air gap of the dimensions of the last magnet. Then the flow of magnetism at the section *a a*, Fig. 4, is calculated, ditto for section *b b*, where it is greater than at *a a*, by the amount which leaks out of the iron between these two sections. Similarly, the flow is obtained at all the sections, *c c*, *d d*, &c., round the circuit, the area of the iron at all these sections being made such that the density of flow has a value for which the magnetic conductivity of the cast steel is high. When the density of the flow is found, having a previous knowledge of the magnetic quality of the steel we can get the permeability for each section. Then the product of current, into number of turns of wire, necessary to force the magetism through all the different sections into which the magnetic circuit has been divided can be found, and, adding all these together, we can obtain the current that must be sent round the magnet a given number of times to produce the desired effect. The following table gives the flow, density of flow, &c., at the different sections (Fig. 4), the "ampere turns," *i.e.* current, into number of turns, given in column 5, being for the particular section, together with the similar one, on the other side of the ring.

For Magnet, Fig. 4.

Section at.	Flow of mag. C.G.S. units.	Area of section, sq. cm.	Density of flow, C.G.S. units.	Current × No. of turns required for section. Ampere turns.
aa	32,000	4·0	8,000	For air gap 6360
bb	64,000	7·2	8,900	very small
cc	126,000	7·2	17,500	120
dd	147,000	12·9	11,400	70
ee	200,000	12·9	15,500	130
ff	225,000	12·9	17,500	320
gg	249,000	18·0	13,800	140
hh	270,000	18·0	15,000	160
ii	270,000	18·0	15,000	170
			TOTAL ...	7470

Column 2 shows what a large amount of magnetism leaks out from the one side of the ring and passes over to the other, not passing through the air gap at all. Column 3 shows how the

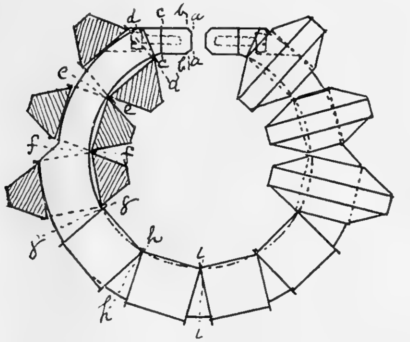

FIG. 4.—(Scale, quarter full size).

area of the iron has to be increased, owing to this leakage, for sections further away from the air gap. The current for this magnet is to be 5·4 amperes, and this flowing 1,500 times round should allow an ample margin to produce the field required.

It is interesting to compare the leading particulars of these two magnets.

Table comparing Two Magnets.

	Original magnet.	New design, Fig. 4.
Strength of field, C.G.S. units	7900	8000
Length of air gap, cm.	1	1
Area of air gap, sq. cm.	4	4
Exciting current, amperes	15	5·4
Turns of wire	3000	1500
Product of current, into number of turns, ampere turns	45,000	8100
Length of wire, yards	1140, No. 11	450, No 16.
Weight of wire, lbs.	139	17
Weight of iron in magnet, lbs.	41	15½
Total weight, iron and copper, lbs. ...	180	33
Cost of iron and copper—Iron @ 2·2*d.* per lb.; copper @ 1*s.* per lb.	£11 9 0	£2 11 0
Cost of working magnet continuously, per year, with current at 6*d.* per Board of Trade unit	£130 0 0	£25 0 0

Since the magnet was intended to work in connection with a submarine cable, it is quite safe to say it would require current throughout the year, and then, as the above table shows, there would be a saving of more than 100*l.* a year by using the magnet, Fig. 4, if the current could be got at 6*d.* per Board of Trade unit—it would, however, very likely cost much more under these conditions—to say nothing of the saving in first cost.

Another example of the importance of having sufficient iron in the magnetic circuit is afforded by the alterations that were made to an electro-magnet belonging to the Central Technical College. The cross section of its yoke was less than half that of the cores, due to the fact that the magnet was made before the theory of the magnetic circuit was understood. Recently a new yoke of proper cross section was made for the magnet, and it was found by experiment before and after the alteration that under precisely the same conditions the strength of the field had been just doubled simply by adding a few pounds of iron in the right place.

But at the same time it should be remembered that the magnetic properties of different specimens of iron vary enormously, and it is important that any iron which is to be used for a magnet should first be tested. Fig. 5 shows a very convenient apparatus for doing this. It consists of a massive iron frame into which you can slide a bar of the sample to be tested, the bar passing through a thin brass tube on which a known number of turns of wire are evenly wound. Also a few turns of fine wire are wound on the middle of the tube, shown at T, Fig. 5,

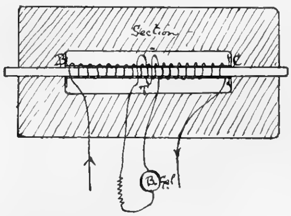

FIG. 5.

and connected to a ballistic galvanometer. A current is sent through the large coil, causing magnetism to flow through the bar, returning by the massive frame the cross section of which is so large that practically the whole of the magnetomotive force due to the current is used to send the magnetism through the bar; therefore, dividing the total ampere turns by the length of the bar we obtain the ampere turns necessary to send the magnetism through one centimetre of that specimen of iron. Several different strengths of current are sent through the magnetising coil, and in each case the flow of magnetism produced is measured by suddenly switching off the current, consequently causing the magnetism passing through the secondary circuit connected to the ballistic galvanometer to rapidly die out, and in doing so a quantity of electricity, proportional to the amount of magnetism, is sent through the galvanometer, thus giving a measure of the amount of magnetism. Fig. 6 shows the difference between three specimens of iron—I. cast iron, II. wrought iron, III. best cast steel for magnets.

The curves show how rapidly the magnetic resistance of iron rises as the density of magnetisation is increased, and therefore the importance of not allowing the density to exceed about

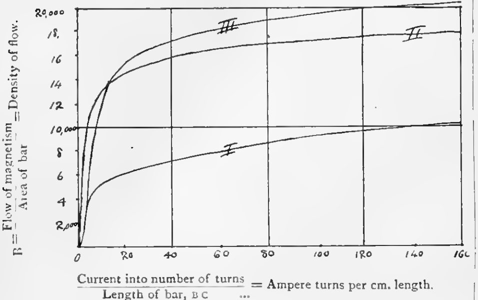

FIG. 6.

16,000 C.G.S. units. These curves are very useful in designing, because from them the ampere turns necessary to produce a certain density of magnetisation in a particular kind of iron can at once be found. It is most important to use the best steel, such as curve III. represents, for making magnets that are to produce very strong fields. With regard to what is meant by a very strong field, a field up to 20,000 C.G.S. units is moderately easily reached. But at about this limit saturation of the iron sets in and it becomes much more

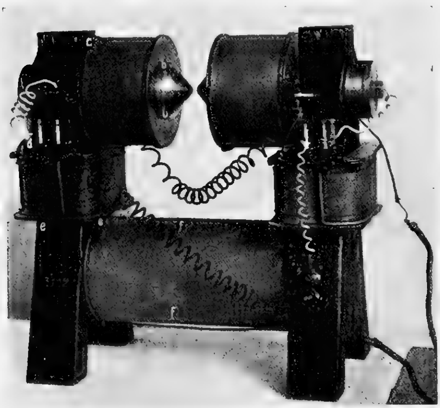

FIG. 7.

difficult to go higher. A field of 30,000 units is a very strong field; the cost of the magnet rises very rapidly if a stronger field than this is required. A field of 40,000 is about the strongest field obtainable. To go above this would require such a large additional expenditure in materials and power, compared with the small increase in the field, that it is not practical.

Fig. 7 shows a photograph of a good type of magnet to produce a very intense field. In this magnet the density of flow in the pole pieces is very great, so great, in fact, that the permeability of the pole pieces is not much greater than that of air; consequently a very large leakage of magnetism occurs, which makes the calculations very laborious. An idea of the amount of leakage that occurs is got from the fact that the flow of magnetism in the lower cylinder, Fig. 7, is fifty times greater than the flow across the air gap under working conditions, whereas in the case of the magnets of dynamo machines the flow in the yoke would not generally be more than 1·4 times the flow in the air gap, because they produce only relatively weak fields of about 6000 units. Owing to this great leakage the calculations cannot be made so accurately for this magnet, Fig. 7, as for dynamo magnets. In making the final calculations for this magnet it was necessary to divide the magnetic circuit in the pole pieces up into a great many sections, only two millimetres apart, finding the ampere turns necessary for each section, because the density changes so rapidly in the pole pieces, and also because the ampere turns required for the pole pieces are much greater than those required for the air gap, which cannot be helped, because the magnet was designed to produce a very intense field in a small air gap.

The following table gives the results of the final calculations:—

For Magnet, Fig. 7.

	Distance of section from pole tip in cm.	Section at.	Total flow of magnetism at section.	Area of section, sq. cm.	Density of flow of mag., C.G.S. units.	Product of current, into number of turns required for each section.
					For air gap 8900	
In pole piece	0	—	27,500	0·785	35,000	4,340
	0·2	—	53,000	1·54	34,400	3,500
	0·4	—	81,500	2·7	30,100	4,140
	0·8	—	139,500	5·7	24,500	763
	1·2	—	208,500	10·5	20,000	175
	2·2	—	375,500	27·3	13,800	24
	3·2	*bb*	535,000	52·75	10,150	660
		cc	925,000	52·75	17,500	183
		dd	1,054,000	80·0	13,100	540
		ee	1,206,000	80·0	15,100	894
		ff	1,374,000	85·0	16,100	
					TOTAL...	24,119

This magnet was originally intended to produce a field of 35,000 C.G.S. units, in an air-gap ⅛-inch long, for which the above calculations were made; but they show that the magnet will not be able to produce so strong a field as this, because it is wound so that it may be connected straight on to 200-volt mains, with all coils in series, or 100-volt mains with two sets of coils in parallel, and then there are 22,400 ampere turns available, whereas at least 24,120 are required.

Recently this magnet was made by the Electric Construction Company for the Solar Physics Laboratory, South Kensington, and the strength of the field produced under the conditions assumed in the above calculation was found to be 32,000 C.G.S. units, showing that the theoretical calculations agree fairly well with practice, considering the very high value of the field.

When the length of the air-gap was reduced to 2 millimetres, and the exciting current doubled, the maximum strength of field attained, for a short time, was nearly 38,000 C.G.S. units, which corresponds to a pull, between the pole pieces, of no less than 830 pounds per square inch! T. L. JAMES.

SOME RECENT WORK ON DIFFUSION.[1]

THE subject of my lecture is one which, though essentially of a physical nature, had its origin in what may be regarded as a no man's land, a strip of neutral territory which can be claimed exclusively neither by the physicists nor the biologists.

An attempt to reconcile some apparently contradictory facts connected with the nutrition of plants has led, somewhat unexpectedly, to an extension of the laws of gaseous diffusion, so that we shall have to deal with one of those comparatively rare cases in which biology has been able to react to some extent on physics.

It has long been known that the primary source of the carbon of all plants is the carbonic acid existing in small quantities in ordinary atmospheric air, and that their green parts, more especially the leaves, are able to utilise the energy of sunlight in decomposing the carbonic acid and water and building up from their elements a whole series of substances, such as sugars and starch, which contribute directly to the nutrition of the plant.

The immediate seat of this synthetic and assimilatory process is found in the minute green chlorophyll granules which occur in great numbers within the cells of the leaf tissue, and one of the first problems to be dealt with in the study of the process is to show in what manner the highly dilute carbonic acid of the air can gain entry into the leaf with sufficient rapidity to supply these assimilating centres with material for the needs of the plant.

In a typical leaf, such as is represented in section in the diagram, both sides are covered with a cuticle and epidermis pierced at regular intervals on one or both sides with extremely minute openings, whose size is capable of being regulated according to the requirements of the plant. These are the *stomates* which open out into a relatively large cavity within the leaf, and this cavity in turn communicates with the numerous and roomy air-spaces between the cells containing the green chlorophyll granules.

One of the most important functions of the stomates is undoubtedly to regulate the transpiration of water from the plant, but the question of how far these minute openings play a part in the interchanges of gases between the interior of the leaf and the outer air has been a subject of very lively controversy.

It is now about thirty years since the eminent French chemist, Boussingault, came to the conclusion that the carbonic acid of the air gains access to the leaf, not through the *stomates*, but through the continuous substance of the cuticle and epidermis, by a process of *osmosis* similar to that by which carbonic acid had been shown by Graham to pass through a thin film of india-rubber.

So convincing did Boussingault's experiments and arguments appear to his contemporaries that this view became an article of faith for something like a quarter of a century, until, in fact, some five or six years ago, when Mr. F. Frost Blackman took up the subject and proceeded most inconsiderately to shatter all the most cherished statements of our text-books on this question.

I regret that time will not allow me to do more than state the general conclusions at which Mr. Blackman arrived and which may be briefly summarised as follows:

In the first place there is no appreciable passage of atmospheric carbonic acid through the surface of a leaf which is naturally devoid of stomates, such, for instance, as the upper surface of a normal leaf, which is quite imperforate; neither is any entry of carbonic acid possible when the stomates have been artificially blocked or made to close spontaneously.

In addittion to this, if a leaf has stomates on both surfaces the relative in-take of carbonic acid by those surfaces bears a distinct relation to the distribution of the stomates.

We can, in fact, no longer doubt that when a leaf is respiring or assimilating mere osmosis of carbonic acid through the substance of the cuticle and epidermis plays little or no part in the gaseous exchanges, and that whatever the exact nature of the process may be it must be carried on exclusively by the minute openings of the stomates.

Since anything like a mass movement of the air through these openings is out of the question, we must look to the phenomena of *diffusion* for the true explanation, and especially to that form of it which was first described by Graham as *free diffusion*, that is to say the natural tendency possessed by gases or liquids to form a perfect mixture when they are in contact with each other and there is no partition of any kind between them.

[1] Discourse delivered at the Royal Institution, Friday, March 22, by Dr. Horace T. Brown, F.R.S.

This spontaneous mixing is quite independent of any currents or mass movements of any kind, and is brought about by the gradual interpenetration of the molecules of the one gas or liquid by the molecules of the other.

As an example of this kind of diffusion I have here a cylinder which a few weeks ago was partly filled with 5 per cent. gelatine solution. After the gelatine had set, the cylinder was filled up with a highly-coloured solution of a copper salt, which you now see has permeated the jelly to a certain depth. There has been no mixing of the solutions in the ordinary sense of the word, for the gelatine is virtually a solid. The effect has been produced by the molecules of the coloured copper salt, by reason of their rapid movement in all directions, gradually penetrating into the spaces between the molecules of the gelatine layer. Given a sufficient length of time and there would be an equal partition of the coloured substance between the two layers.

Diffusion takes place, as is well known, much more rapidly with gases than with liquids. Had our cylinder contained, for instance, carbonic acid in the lower half and air in the upper, a complete mixing would have taken place in a comparatively short time, even if all convection currents had been prevented.

The classical researches of Graham on the diffusion of gases through thin porous septa established the general law that the rate of diffusion of the different gases, under identical conditions, varies inversely as the square roots of their respective densities. Graham's results, however, only acquaint us with the *relative* velocities of diffusion, whereas for the particular problem which we have before us we must know the *absolute* velocities of diffusion under strictly defined conditions.

It is mainly to the Viennese school of physicists, and especially to Prof. Loschmidt, that we owe our present knowledge of the actual rate of penetration of one gas by another in free diffusion.

By observing the speed with which different pairs of gases spontaneously mix in a tube, Loschmidt was able to deduce certain *absolute values* expressing the velocity of their interpenetration.

Some of these results for different pairs of gases are given in the diagram, the last column representing the "constant of diffusivity" expressed in centimetre-gram-second units.

Let us consider the constant for carbonic acid and air, which at 0° C. is ·142. This means that when air and carbonic acid gas are freely diffusing into each other, an amount of either gas corresponding to ·142 cubic centimetre will pass in one second of time across an area of one square centimetre when the partial pressure of the gas varies by one atmosphere in one centimetre of length.

Now when we come to apply these absolute values of diffusivity to the passage of the extremely dilute CO_2 of the air into the leaf stomates (whose dimensions can of course be determined), we find that free diffusion through these openings is apparently able to account for only a portion of the gas which we know must enter the leaf, unless we make some extremely improbable assumptions as to the very low point at which the partial pressure of the carbonic acid is maintained immediately under the apertures.

I shall not, however, trouble you with the calculations on which this statement is based, since I prefer to put the matter in a more concrete form, which has also the advantage of emphasising the extraordinary power which an assimilating leaf possesses of extracting carbonic acid from its surrounding air.

There are two methods by which we can determine the actual amount of atmospheric carbonic acid used up by an assimilating leaf, one a direct the other an indirect method.

Part of the apparatus used in the direct method is shown on the table.

The leaf, which may be still attached to the plant, is enclosed in a glazed case, through which a measured current of air is drawn of which the carbonic acid content is accurately known. When the air emerges from the case it passes through an absorption apparatus, which retains the whole of the CO_2 left in the air after passing over the leaf. This absorbed carbonic acid is determined at the close of the experiment, and we then have all the data for estimating the carbonic acid abstracted from the air by the leaf. The area of the leaf being known, the CO_2 absorbed can be referred to a unit area of leaf and a unit time.

By the indirect method, which is due to Sachs, the actual increase in dry weight of a given area of an assimilating leaf is determined, and since this increase in weight is due to substances having a definite percentage of carbon a simple calculation enables us to determine the equivalent amount of carbonic acid abstracted from the air.

By such methods as this it can be shown that an actively assimilating leaf, such as that of the Catalpa tree, in full daylight, and under favourable conditions of temperature, can take in carbonic acid from the air at the rate of about 1/10th cubic centimetre per hour for each square centimetre of leaf.

Since there are only about three volumes of carbonic acid in 10,000 volumes of ordinary air, this must mean that in a single hour the under surface of the leaf will take in as much carbonic acid as is contained in a column of air about eight feet long, and having the same area of cross-section as the leaf.

But this remarkable power of an assimilating leaf will be better appreciated if we compare it with a liquid surface of a strong solution of caustic alkali, which is known to have such a great avidity for carbonic acid.

We can investigate the absorptive power of such solutions for the carbonic acid of the air under fixed and controllable conditions by using a form of apparatus which I have on the table, and which can be examined at the close of the lecture. It is so arranged that an air current of known velocity can be drawn over the surface of the absorbing solution which has a known area.

When a very low velocity of the air current has been reached the amount of absorption becomes constant at ordinary temperatures at about ·17 c.c. of carbonic acid per square c.m. of surface per hour.

So we see that a leaf, assimilating under natural conditions, is taking in carbonic acid from the air more than half as fast as a surface of the same area would do if it were wetted with a constantly renewed film of a strong solution of caustic alkali submitted to a strong current of air.

This is in itself a somewhat remarkable conclusion, but what are we to say to a proposition which would limit the absorptive power of the leaf surface to the extremely small apertures of the stomates?

In a leaf such as we have been considering, the aggregate area of the openings of the stomates, when expanded to their widest, amounts to less than *one per cent.* of the total leaf surface, so that if the entry of the CO_2 takes place exclusively by these openings we must conclude that it goes in more than fifty times faster than it would do if the mouth of each one of these minute openings were filled with a constantly renewed solution of strong caustic alkali.

Such facts make it difficult unreservedly to accept the view that the gaseous exchanges in leaves are really carried on exclusively by the stomates, which occupy such a small fraction of the leaf surface. On the other hand, the direct experimental evidence in favour of this view is overwhelming, so that we apparently find ourselves on the horns of a dilemma.

There appeared to be only one way out of the difficulty, that was to assume that the leaf knows more about the laws of free diffusion than we do, and has adapted itself to some physical principles which have hitherto escaped notice. This was found to be the case when the structure of the leaf was regarded as a piece of physical apparatus for promoting rapid diffusion.

I do not propose to take you through the various and tedious stages by which the true explanation was reached, but will attempt, as far as possible, to short-circuit the current of the argument.

In the first place I wish to call your attention to a particular mode of free diffusion which, in gases, has been but little studied, but which has a very direct bearing on diffusion in the living leaf, where one of the constituents of the diffusing gases, the carbonic acid, is very small in amount compared with the others.

Let us for a moment concentrate our attention on the air which is contained in this open glass cylinder, and endeavour to picture to our minds the jostling crowds of the perfectly elastic molecules of the various gases, flying hither and thither in all imaginable directions and coming into frequent collision with each other and the sides of the containing vessel.

Now in this jostling throng there is a certain proportion of molecules of *carbonic acid*, which we will imagine for the moment are distinguished from the molecules of the other gases by some difference in colour—let us suppose them to be *green*.

Now further consider a plane surface in the contained air of the cylinder; from the dynamical theory of gases it follows that in any given interval of time, temperature and pressure remaining constant, the same average number of the "green" molecules will cross this imaginary plane in opposite directions, and since this will be true for any plane surface, no matter where we take it within the cylinder, there can be no change in the average distribution of the "green" molecules throughout the cylinder—in other words, no change in any part of the cylinder in the composition of the air as regards its carbonic acid content.

But now let us imagine that the bottom of the cylinder is suddenly made capable of absorbing carbonic acid, say by the introduction, without any disturbance of the air, of a little solution of caustic soda or caustic potash. The "green" molecules which now strike the bottom of the cylinder at all imaginable angles of incidence will not all rebound as they originally did, but will be to a large extent trapped in their to and fro excursions, so that in the very first brief interval of time a very thin stratum of air, parallel to and immediately above the absorbing surface, will be partially freed from its "green" molecules.

Now consider the kind of exchange of "green" molecules which occurs in the next very brief interval of time between this partially depleted layer at the bottom and the one immediately above it. The rate of exchange across the imaginary plane dividing these two contiguous layers can no longer be equal and opposite since the number of "green" molecules in the upper stratum is greater than that in the lower. A larger number of the "green" molecules must consequently pass in a given brief interval of time from the higher to the lower stratum than from the lower to the higher; in other words, the *balance of exchange* is in favour of the lower layer. This state of affairs will rapidly propagate itself upwards until the mouth of the cylinder is reached, and, provided the air outside the cylinder is kept of the same composition and the absorptive power of the bottom of the cylinder is also kept constant, these *uncompensated balances of exchange* between the imaginary layers may be regarded as constituting a steady *flow* or *drift* of the "green" molecules down the tube towards the absorbent surface.

Although within the column there is this constant flow of carbonic acid molecules in the general direction of the axis of the tube, the system as a whole may now be regarded as static as long as all the conditions remain unchanged. The flow is, then, strictly analogous to the "flow" of heat in a bar of metal which is kept with its two ends at a uniform difference of temperature, or to the flow of electricity in a conductor between two regions maintained at a constant difference of potential; and static diffusion admits of precisely the same simple mathematical treatment as these phenomena of conduction of heat or electricity when we come to its quantitative study.

In such an imaginary experiment as we have been considering it is clear that the amount of carbonic acid in the air of the cylinder must vary uniformly from a maximum at the top of the cylinder to a vanishing point at the bottom, so that if the CO_2 really had the green colour which, for purposes of argument, we have attributed to it, the depth of colour of the air column would uniformly diminish from top to bottom.

This can be illustrated by the diffusion of a coloured copper salt down a gelatine column. If this column were cut off just where the colour ceases to be perceptible, and the cut end were immersed in water to carry off the diffusing salt as fast as it came through the column, then if the upper end of the column remained in contact with the coloured copper solution we should ultimately get a constant steady flow of the salt down the column.

Under these conditions it can be readily shown, both experimentally and theoretically, that the actual amount of substance diffusing down the column in a given time will, in the first place, be directly proportional to the difference in the concentration of the diffusing substance at the two ends of the column; it will also be directly proportional to the *area* of cross-section of the column, but inversely proportional to its length.

The fact which for the moment I wish you to bear in mind is that, all other things being the same, the amount of diffusion down a column of this kind *varies directly as the area of the cross-section of the column.*

This is roughly illustrated by these two cylindrical columns of gelatine of different diameters, down which a coloured solution has been diffusing for equal times.

The salt has penetrated both columns to the same depth, and the gradation of colour is also the same, a proof that the rates of diffusion down the columns must be proportional to their areas of cross-section.

But now let us consider what will happen if instead of varying the width of the column throughout its entire length we only partially obstruct the cylinder somewhere in the line of flow, say by means of a thin diaphragm pierced with a single circular hole of less diameter than the bore of the tube.

We must resort to experiment to answer this question.

Suppose we take a series of exactly similar flasks, such as I have here, and produce a steady flow of atmospheric carbonic acid down their necks by partially filling each flask with a solution of caustic soda, the amount of carbonic acid entering the flasks being determined by subsequent titration of the soda solution. We can then study the effect produced by partially obstructing the mouths of the flasks with thin discs of metal or celluloid pierced with a single hole of definite size.

The results of a series of experiments of this kind are given in Table I., and you will see that under these conditions the amounts of carbonic acid diffusing down the cylindrical necks in a given time are not proportional to the areas of the apertures, as might reasonably have been expected, but are directly proportional to their *diameters*.

TABLE I.

Diffusion of Atmospheric CO_2 through single apertures of varying size.

Diameter of Aperture	CO_2 diffused per hour	CO_2 diffused per sq. cm. per hour	Ratio of Areas	Ratio of Diameters	Ratio of CO_2 diffused
mm.	c.c.	c.c.			
22·7	·2380	·0588	1·00	1·00	1·00
6·03	·0625	·2186	·07	·26	·26
3·23	·0398	·4855	·023	·14	·16
2·11	·0260	·8253	·008	·093	·10

This, of course, implies that as we make the aperture smaller the flow through a given unit of its area is proportionately increased; in other words, the acceleration of flow is *inversely proportional to the diameters of the apertures*.

This unexpected fact, which lies at the root of the whole question we are considering to-night, may be experimentally illustrated in a variety of ways.

We may, for instance, cause the aqueous vapour of the air to diffuse into a similar series of flasks, using in this case strong sulphuric acid as the absorbent, and determining the amount of diffusion of the water vapour by weighing the flasks from time to time. You will see from the results of such an experiment that the diffusion rates again follow pretty closely the ratios of the diameters of the apertures, and are widely divergent from the ratios of areas. (See Table II.)

TABLE II.

Diffusion of Aqueous Vapour through apertures of varying size.

Diameter of Apertures	Ratio of Areas	Ratio of Diameters	Ratio of Diffusion for equal times
mm.			
2·117	1·0	1·0	1·0
3·233	2·3	1·52	1·55
5·840	7·6	2·75	2·54

This "diameter law" is also applicable to circular liquid surfaces, the amount of absorption or evaporation from such surfaces varying, under certain conditions, not in accordance with the area of the surfaces, as might have been expected, but with their diameters.

I have here a short burette-like tube with a wide rim of metal round the top. When this tube is completely filled by letting in a solution of caustic soda we have a circular surface of the solution lying in the same plane as the rim. When this has been exposed to the air for a given time the carbonic acid absorbed by the disc of liquid can be determined by drawing off and titrating.

If such absorptive discs of different dimensions are exposed to air which is in *slight movement*, we shall find that the carbonic acid absorbed is proportional to the *area* of the surface. The smaller, however, we make the discs, and the greater precautions we take to keep the air over them perfectly still, the nearer do the absorptions become proportional to the diameters. (See Table III.)

There is always, however, more difficulty in obtaining these results with plane absorbing surfaces than by diffusion through a perforated diaphragm. The reason for this will be apparent later.

TABLE III.

Absorption of Atmospheric CO_2 by Circular Surfaces of Solutions of Caustic Alkali.

Diameter of Surface mm.	Ratio of Areas.	Ratio of Diameters.	Mean Ratio of Areas and Diameters.	Ratio of CO_2 absorbed.
10·25	1·0	1·0	1·0	1·0
20·25	3·9	1·9	2·9	3·0
29·25	8·1	2·8	5·4	5·3
40·00	15·2	3·9	9·5	9·2
5·0	1·0	1·0	—	1·0
10·25	4·2	2·05	—	2·47

Before entering on an explanation of these facts I wish you to note a very important conclusion to be drawn from them, and one which readily admits of experimental verification.

We have seen that when we partially obstruct the diffusive flow of a gas or liquid by a thin septum with a single circular perforation, the velocity of the flow through each unit area of aperture increases as the diameter of the aperture decreases.

One might, therefore, expect that if a number of fine holes were suitably arranged in such a septum, the acceleration of flow through the individual holes might assume such proportions that a perforated septum of this kind would exercise little or no obstruction on the diffusive flow, although in such a case the aggregate area of the holes might only represent a small fraction of the total area of the obstructing septum.

Strange and paradoxical as such a conclusion may at first sight appear, it will bear the test of experiment.

I have here a thin film of celluloid; in fact, a piece of the ordinary Kodak roller-film. This has been perforated with holes about ·4 millimetre in diameter, arranged at a little more than 2·5 diameters apart, so that there are just one hundred of such perforations on a square centimetre of area. The clear holes represent about 1/10th of the area of the film, 9/10th of the sieve being blocked up with impervious celluloid.

Here are two columns of gelatine, down which a blue solution of copper-ammonium sulphate has been diffusing for equal times. One of these columns is unobstructed in any way, being in direct contact with the coloured liquid. In the other case a finely perforated celluloid film has been interposed, which has the effect of blocking out 9/10ths of the cross-section of the column. You see that, notwithstanding this, there is no appreciable difference in the amounts of coloured salt which have diffused in the two cases; the salt has, in fact, gone through the finely-pierced septum as readily as if no obstruction were present.[1]

We find that exactly the same holds good with gaseous diffusion.

If finely perforated septa of this kind are luted on to short tubes containing caustic soda and are exposed to still air, the amount of carbonic acid diffusing through the holes in the diaphragm can be compared with the amount which we know would diffuse down the open tube under like conditions.

Some results of this kind are given in Table IV.

[1] The celluloid film is itself not permeable.

TABLE IV.

Diffusion of Atmospheric CO_2 through Multiperforate Septa into Tube 4 c.m. long. Diameter of Holes ·380 m.m.

No. of Holes per sq. cm.	Diameters Apart.	CO_2 Diffusing through Septum per hour c.c.	Open Tube Diffusion per hour c.c.	Percentage of Septum Diffusion on Open Tube Diffusion.	Percentage area of Cross-section occupied by Holes.
100	2·63	·361	·346	104·3	11·34
25	5·26	·148	·342	43·2	2·82
11·11	7·8	·131	·352	37·2	1·25
6·25	10·52	·110	·353	31·1	·70
15·7	15·7	·068	·334	20·4	·31

I must now ask you to follow me in a somewhat theoretical excursion in quest of an explanation of these curious facts.

(To be continued.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following have been elected public examiners:—Mr. R. T. Glazebrook, in physics; Mr. P. Elford, in chemistry; Prof. F. Gotch, in physiology.

The curators of the University Chest have been authorised to spend a sum not exceeding 1400*l.* in certain extensions of the Chemical Department which are necessitated by the loss of the laboratory known as the "Glastonbury Kitchen." The latter is now required as access to the new Radcliffe Library.

A proposal to permit candidates for the degree of Bachelor of Letters or Science to keep more than one term of University residence in the year by residence during the vacation has been rejected.

A proposal to provide access for wheeled traffic to the Departments of Physiology, Human Anatomy and Pathology at the back of the University Museum has also been rejected owing to the opposition of those who regard this as an encroachment upon the University Park.

The Junior Scientific Club held their 226th meeting on May 31. A paper was read by E. Walls, entitled "The Quest of the Philosopher's Stone." Prof. Silvanus Thompson delivered the Boyle Lecture on June 6, on "Magnetism in Growth."

CAMBRIDGE.—In the mathematical tripos, part i., the senior wrangler is Mr. A. Brown, of Caius College, a Ferguson student from Edinburgh. Miss Reynolds, of Newnham, is bracketed 11th wrangler. Three names appear in the first class of part ii.: Mr. J. E. Wright, Trinity (senior wrangler 1890); Mr. T. H. Havelock, St. John's (15th wrangler); and Mr. J. Chadwick, Pembroke (5th wrangler). Miss W. M. Hudson, Newnham, is in the first division of the first class (bracketed 8th wrangler 1890).

The professor of pathology announces ten separate courses of lectures and practical work to be given in the long vacation, beginning July 8.

PROF. R. W. WOOD, of the University of Wisconsin, has been appointed professor of physics in the Johns Hopkins University, in succession to the late Prof. H. A. Rowland.

WE learn from *Science* that the Wisconsin Legislature has granted 210,000 dollars to the University of Wisconsin, at Madison, in addition to the regular income previously derived from the State. Of this sum 150,000 dollars is for a new building for the College of Agriculture, which is to house the administration offices of this department and the experiment station as well as the departments of bacteriology and chemistry. This College also receives 10,000 dollars annual increase to its present income. The College of Engineering receives 30,000 dollars for equipment of its new building, which was provided by the last Legislature; also 7500 dollars annual increase in income. The newly organised School of Commerce secures 3500 dollars annual increase.

DR. H. M. KYLE has been appointed naturalist to the Marine Biological Association and fisheries' instructor for the county of Devon. Dr. Kyle is a distinguished graduate of the University of St. Andrews, having gained the rector's prize for an essay on evolution and having held successively the Fisheries' prize, the Berry scholarship (100*l.*) and, for three years, the Exhibition of 1851 scholarship (150*l.*) for original researches in connection with the fisheries. His studies for seven years have been devoted to marine zoology and the scientific treatment of the problems of the fisheries at the chief marine laboratories of Europe, including Naples, Plymouth, &c., and both the old laboratory and the new (Gatty) laboratory at St. Andrews, where he was trained.

WE learn from the *Berliner Klinische Wochenschrift* that the second annual congress of the German Association for School Hygiene, which was founded about two years ago for the purpose of studying and promoting all matters relating to health and hygiene in connection with schools, was held at Wiesbaden on May 31. The municipal authorities of that city placed the "Curhaus" at the disposal of the council of that association, where all the official meetings were held during the congress. The attendance was a large and a representative one, and the programme contained many important and highly instructive subjects, of which the following may particularly be mentioned: (1) the new Prussian school reform in relation to school-hygiene; (2) the hygienic condition of German schools in general, with special reference to that of Wiesbaden; (3) the prevention of infectious diseases regarded from a general point of view, with special reference to the spread of tuberculous affections amongst school children.

THE *Educational News* of Scotland states that the following is the list of candidates for the chair of natural philosophy in Edinburgh University, vacant through the resignation of Prof. Tait:—Prof. J. C. Beattie, South African College, Cape Town; Prof. G. H. Bryan, F.R.S., University College, North Wales; Dr. Charles Chree, F.R.S., National Physical Laboratory, Richmond; Dr. Cargill G. Knott, University of Edinburgh; Prof. J. P. Kuenen, University College, Dundee; Dr. Charles H. Lees, Owens College, Manchester; Mr. David B. Mair, Civil Service Commission, London; Prof. J. A. M'Clelland, University College, Dublin; Prof. J. G. MacGregor, F.R.S., Dalhousie University, Halifax, U.S.A.; Prof. Karl Pearson, F.R.S., University College, London; Mr. G. F. C. Searle, Cambridge; Mr. George W. Walker, Cambridge; Mr Gilbert T. Walker, Cambridge; Mr. C. T. R. Wilson, F.R.S., Cambridge.

PROF. RAMSAY expressed the views of a number of teachers and investigators in the annual oration delivered by him at University College, London, last week, on "The Functions of a University." The essential principle of University work should be research. This, said Prof. Ramsay, should be the goal to be clearly kept in view in the philosophical faculties of Universities. He was not one of those who would urge that a young man should not learn a great deal of what had been already discovered before he attempted to soar on his own wings. But there was all the difference in the world between the point of view of the student who read in order to qualify for an examination, or to gain a prize or scholarship, and the student who read because he knew that thus he would acquire knowledge which might be used as a basis of new knowledge. It was that spirit in which our Universities were so lamentably deficient; it was that spirit which had contributed to the success of the Teutonic nations, and which was beginning to influence the United States. A University which did not increase knowledge might be a technical school or a coaching establishment, but it had no claim to the name University. The best way of fitting young men for the manifold requirements of the Empire was to give them the power of advancing knowledge.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, May 16.—Prof. Emerson Reynolds, president, in the chair.—The following papers were read:—Derivatives of methylfurfural, by H. J. H. Fenton and Miss M. Gostling. A simple method of obtaining pure methylfurfural is described.—Optically active nitrogen compounds and their bearing on the valency of nitrogen; dextro- and lævo-α-benzylphenylallylmethylammonium salts, by W. J. Pope and A. W. Harvey. The authors have prepared in a state of purity a number of substances owing their optical activity to the presence of an asymmetric nitrogen atom; it is shown that *d*- and *l*-benzylphenylallylmethylammonium iodides and bromides slowly become optically inactive when preserved in chloroform solution.—Reactions of hydroxyoxamides, by R. H. Pickard and W. Carter. Hydroxyoxamide and its phenyl-, tolyl- and naphthyl-derivatives give the general reactions of hydroxamic acids and are thus quantitatively convertible into substituted biurets and allophanates.—The *sym*-trichlorobromoanilines, and chloro- and bromo-amino-derivatives of chlorobromoacetanilides, by F. D. Chattaway and K. J. P. Orton. The authors call attention to the great resemblance existing between the two similarly constituted *sym*-chlorodibromoanilines, their acetylderivatives and the two *sym*-dichlorobromoanilines respectively.—Replacement of bromine by chlorine in anilines, by F. D. Chattaway and K. J. P. Orton.—The absorption spectra of cyanogen compounds, by W. N. Hartley, J. J. Dobbie and A. Lauder. An examination of the absorption spectra confirms the view that cyanuric acid and methyl cyanurate are similarly constituted, and indicates that the relations between melamine and triethylmelamine are correctly represented by the commonly accepted formulæ.—The nutrition of yeast. Part iii. By A. L. Stern. The author concludes that any increase of nitrogenous or inorganic nutriment beyond a definite limit will not increase either the amount of nitrogen assimilated by yeast or the weight of the yeast; any increase of the added sugar, however, is accompanied by an increase both in the amount of nitrogen assimilated and in the weight of the yeast. The growth of yeast proceeds as long as any sugar remains unfermented and is, during part of the fermentation, proportional to the amount of sugar fermented.—On the colloid form of piperine, with especial reference to its optical refraction and dispersion, by H. G. Madan. On cooling piperine, after heating to 180° for an hour, it remains in the colloidal state for an indefinite time; the colloid has a high refractive index ($\mu_D = 1{\cdot}684$) and exhibits an extraordinarily high dispersive power.—Note on pyromucylhydroxamic acid, by R. H. Pickard and A. Neville.—The condensation of ethylphenylketone with benzaldehyde, by R. D. Abell. Ethylphenylketone and benzaldehyde condense in presence of sodium ethoxide with formation of 1:3-diphenyl-2-methyltrimethylene glycol, benzalpropiophenone and 1:3-dimethyl-1:3-dibenzoyl-2-phenylpropane.—A new method for the determination of hydrolytic dissociation, by R. C. Farmer. The author's method of ascertaining the extent of hydrolytic dissociation depends upon determinations of the free acid or base by distribution between two solvents, one of which dissolves only one of the dissociation products.—The production of some new metallic borides, by S. A. Tucker and H. R. Moody. Crystalline borides having the compositions Zr_3B_4, CrB, WB_2 and Mo_3B_4 are prepared by heating the corresponding metal with boron in the electric furnace.—The action of lead thiocyanate on the chlorocarbonates. Part ii. Carboxymethyl- and carboxyamylthiocarbimides and their derivatives, by R. E. Doran.—The chlorine derivatives of pyridine. Part vii. Some condensation products, by W. J. Sell and F. W. Dootson.—The diazotisation of dinitroanisidine and the constitution of the resulting product, by R. Meldola and J. V. Eyre.

MANCHESTER.

Literary and Philosophical Society, May 28.—Prof. Horace Lamb, F.R.S., vice-president, in the chair.—The influence of grinding upon the solubility of the lead in lead fritts, by Dr. T. E. Thorpe, C.B., F.R.S., and Mr. Charles Simmonds. The paper was a criticism of the methods and conclusions contained in a paper by Messrs. Jackson and Rich, read before the Society in October last. The argument of that paper was stated to rest on the assumption that a fritt behaves as a single chemical compound—an untenable assumption. The theory that as a fritt is dissolved by acid a layer of silica is formed on the outside of the particles, protecting them from further action, was opposed as not being in accordance with facts which are easily demonstrated. The particular fritts used by Messrs. Jackson and Rich in their experiments were of somewhat high solubility, and the conclusions arrived at did not hold for those of lower solubility. A fine powder was, indeed, somewhat more soluble than a coarse one, but the variations of solubility of slightly soluble glazes between the limits of fineness occurring in actual practice were of inconsiderable magnitude. Further, whether or not the solubility varied to some extent with the fineness, the matter was of no practical consequence, since glazes could be obtained, and were in use, which were of the fineness used in working and conformed to the limit of solubility suggested by the Home Office. In the discussion which followed Mr. Burton pointed out that even if grinding only produced—as in experiments actually made with fritts of solubility below the Home Office standard—variations of solubility of some 50 per cent., a fritt not far within the limit would be dangerous in use or not according to the fineness of grinding. He also denied that the more soluble fritts are the softer, as alleged by Dr. Thorpe, but stated that the opposite was the fact. He referred to the danger of lead poisoning from inhaled lead dust, a matter in which solubility in dilute acid did not come into account. Mr. Jackson stated that the finer portions of the fritts dealt with by himself and Mr. Rich contained not more but less lead oxide than the coarser portions, contrary to the suggestions of Dr. Thorpe. He mentioned that he had himself found solubilities of from below 2 per cent. to about 5 per cent. from the same fritt at different grindings, the fritt being one which had been passed by Dr. Thorpe as within the Home Office limit. He showed some photographs of glasses acted on by hydrofluoric acid, showing crystalline forms suggestive of distinct heterogeneity even in the clearest glass, and stated that he had certainly not treated the fritts as single chemical substances.

PARIS.

Academy of Sciences, June 5.—M. Fouqué in the chair.—New researches on the neutralisation of phosphoric acid, by M. Berthelot. When an excess of a solution of lime is added to phosphoric acid, the calcium phosphate precipitated has at first the composition $Ca_3(PO_4)_2$, but in presence of an excess of lime a more basic salt is gradually formed, which finally approximates to the composition $H_3PO_4.2CaO$. An analogous compound has been observed in nature, the oxychloride $CaCl_2$, 3CaO. Similar compounds appear to be formed with baryta.—New researches on the alloys of gold and silver and of other materials arising from Egyptian tombs, by M. Berthelot. Analyses of fragments of gold of the eleventh, twelfth and thirteenth dynasties, of a supposed perfume, and of a copper alloy.—On the magnetic analysis of the radium rays and of the secondary radiation provoked by these rays, by M. Henri Becquerel. A development of the method described in a previous paper.—The physiological action of the radium rays, by MM. Henri Becquerel and P. Curie. Radiferous barium chloride carried on the arm in a thin guttapercha envelope caused at first a reddening of the skin resembling a burn, but without pain. After some days the area of this increased and the skin was broken, and fifty-two days after the action of the rays there still remained a sore. In another experiment with a more active material, the effect of the rays was felt through a glass tube containing the material, a box and the clothes. Inflammation with suppuration was produced in this case after only six hours' exposure to the rays, the wound produced not being entirely healed until forty-nine days after the exposure.—The changes in direction and velocity of an air current which has encountered bodies of divers forms, by M. Marey.—On regressive erosion in the chain of the Andes, by M. de Lapparent. Owing to the possibility of rapid variation of the watershed in this region, the line marking the watershed between the Pacific and Atlantic Oceans, as it exists to-day, does not constitute a true geographical boundary.—On the tellurides of gold and silver in the region of Kalgoorlie in Western Australia, by M. Ad. Carnot. Some analyses of the West Australian minerals sent to the Paris Exhibition. With the exception of some traces of mercury and copper these are practically double tellurides of gold and silver of the type $(Au, Ag,)Te_2$.—On the longitudinal and transversal waves in perfect fluids, by M. P. Duhem.—Contribution to the theoretical and experimental study of liquid veins deformed by obstacles, and on the determination of the lines of induction in a magnetic field, by Prof. H. S. Hele-Shaw. A description of the author's method of photographing stream lines, with three examples. The method not only allows of the verification experimentally of many of the results deduced theoretically in hydrodynamics, but also furnishes a complete solution of many problems of practical importance which it is impossible to attack by mathematical analysis.—Determination of the surfaces which are at the same time surfaces of Joachimsthal and surfaces of Weingarten, by M. L. Raffy.—Observations on electric resonance in rarefied air, by M. Albert Turpain.—The influence of temperature on the electromotive force of magnetisation, by M. Rene Paillot. Using the method described in a previous paper, it was found that the electromotive force of magnetisation of soft iron increases with the temperature, this variation with the temperature being greater as the field is more intense. With bismuth the opposite effect is observed, the electromotive force of magnetisation falling off as the temperature is raised.—The action of the X-rays on conductors and on insulators, by M. J. Semenow. —On the alloys of aluminium. Compounds of aluminium with molybdenum, by M. Leon Guillet. By reducing molybdic acid with a large excess of aluminium three definite compounds were obtained corresponding to the formulæ Al_4Mo, $AlMo$, Al_7Mo, analyses of which are given.—On the alloys of aluminium and magnesium, by M. Boudouard. A set of determinations of the melting points of thirteen aluminium-magnesium alloys ranging from pure aluminium to pure magnesium. The curve of results presents three minima and two maxima, pointing to the existence of two definite compounds, $AlMg_2$ and $AlMg$.—On the cellular structure of some metals, by M. G. Cartaud.—Acidimetry of phosphoric acid by baryta, strontia and lime, by M. J. Cavalier. —On the aluminium contained in mineral waters, by M. F. Parmentier. The author points out that in spite of numerous analyses of the waters from Puits Chomel and Grande Grille the presence of aluminium in notable quantity has been overlooked.—The action of isobutylene bromide on benzene in presence of aluminium chloride, by M. F. Bodroux. The principal products are a butyl-benzene and dimethyl-phenyl-benzyl-methane.—The action of the alkyl malonic esters upon the diazoic chlorides, by M. G. Favrel. Ethyl-methylmalonate, treated with a solution of diazobenzene chloride in presence of sodium acetate, gives the phenylhydrazone of ethyl pyruvate. Diazoparatoluene gives an analogous reaction.—On a new mode of decomposition of bisulphite derivatives, by MM. P. Freundler and L. Bunel. Alkaline nitrites may replace the alkaline carbonates in this reaction —On the secondary products formed in the action of sulphuric acid upon wood charcoal, by M. A. Verneuil. The tetra-, penta- and hexa-carboxylic acids of benzene can be isolated from the residue.—On a new gregarian parasite of the mussel, by M. Louis Leger.—On the cilia of the Ctenophoræ and on ciliary insertions in general, by M. P. Vignon.—Experimental researches on the respiration of annelids. Study of *Spirographis Spallanzanii*, by M. Bounhiol. —The defensive or odorous glands of the cockroach, by M. K. Bordas.—On the structure of the shoot in ligneous plants, by M. Marcel Dubard.—On the proportion of water compared with the ripening of ligneous plants, by M. F. Kövessi.—On the electrolysis of animal tissues, by M. Édouard Branly.—The sources of iodine in the organism. The biological cycle of this metalloid, by M. P. Bourcet.—A method of preparing low brewery yeasts fermenting at a high temperature, by M. Georges Jacquemin.—The otoliths and audition, by M. Pierre Bonnier. —A case of trichosporia (*piedra nostras*) observed in France, by M. Paul Vuillemin.—On the thunderstorm in Paris of May 29, by M. J. Jaubert.

DIARY OF SOCIETIES.

THURSDAY, JUNE 13.

ROYAL SOCIETY, at 4.30.—Bakerian Lecture: Prof. James Dewar, F.R.S. —The Nadir of Temperature and Allied Problems. (1) Physical Properties of Liquid and Solid Hydrogen; (2) Separation of Free Hydrogen and other Gases from Air; (3) Electric Resistance Thermometry at the Boiling Point of Hydrogen; (4) Experiments on the Liquefaction of Helium at the Melting Point of Hydrogen; (5) Pyro-Electricity, Phosphorescence, &c.

MATHEMATICAL SOCIETY, at 5.30.—Remarks on the Quartic Curve $2\alpha^3\beta+m\beta^3\gamma+n\gamma^3\alpha=0$: A. B. Basset, F.R.S.—The Theory of Cauchy's Principal Values, II.: G. H. Hardy.—The Rational Solutions of the Equation $u^3+v^3+w^3+p^3=0$: Prof. Steggall.—Invariants of Curves on the same Surface, in the Neighbourhood of a Common Tangent Line: T. Stuart.

FRIDAY, JUNE 14.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Observations of Mars made at Mr. Edward Crossley's Observatory, Bermerside, Halifax, during the Opposition of 1900–01: J. Gledhill.—A Modified Form of Revolving Occulter for Adapting the Exposure of the Sun's Corona to its Actinic Intensity at all Distances from the Moon's Limb: D. P. Todd.—The Oxford Determinations of Stellar Parallax—Reply to Prof. Turner: Sir D. Gill.—Sun-spots and Magnetic Disturbance: W. Ellis.—Observations of Nova Persei made at Birr Castle, Parsonstown: The Earl of Rosse.—Secular Variation in the Period of R. Carinæ: A. W. Roberts.—The Great Comet of 1901, as observed at the Royal Observatory, Cape of Good Hope: Sir D. Gill.—The Oxford Determinations of Stellar Parallax—Further Reply to Sir D. Gill: H. H. Turner.—Measures of Double Stars made at Mr. E. Crossley's Observatory, Bermerside, Halifax: J. Gledhill.—Corrections to reduce the Revised Madras Catalogue of Stars for 1835·0 to the Fundamental Catalogue of Auwers: A. M. W. Downing.—The Lyrids, 1901 April, observed at Cambridge: J. C. W. Herschel.

PHYSICAL SOCIETY, at 5.—On Herr Jahn's Measurements of the Electromotive Force of Concentration Cells: Dr. R. A. Lehfeldt.—Exhibition of a Set of Specimens of Jena Glass: Prof. S. P. Thompson, F.R.S.

MALACOLOGICAL SOCIETY, at 8.—Notes on *Ariophanta*, *Xestina*, *Nilgiria* and *Euplecta*: W. T. Blanford.—Pleistocene Shells hitherto unrecorded from the Raised Beach of Perim Island, Red Sea: Rev. R. Ashington Bullen.—On a Dibranchiate Cephalopod from the London Clay of Sheppy: G. C. Crick.—(1) Description of a New Species of *Acanthochites* from South Africa; (2) Description of a New Species of Helicina from the Pelew Island: E. R. Sykes.—On the Anatomy of *Helix politissima*, Pfeiffer, and its Generic Position in the Ariophantinæ: Lieut.-Colonel H. H. Godwin-Austen.

TUESDAY, JUNE 18.

ZOOLOGICAL SOCIETY, at 8.30.—Observations on some Mimetic Insects and Spiders from Borneo and Singapore: R. Shelford.—Further Researches upon the Molluscs of the Great African Lakes: J. E. S. Moore. —On the Collections of Birds made by Dr. Donaldson Smith in Northern Somali-land: Dr. R. Bowdler Sharpe.

MINERALOGICAL SOCIETY, at 8.—On the Anharmonic Ratio of Four Faces in a Zone: Alfred Harker —On the Arrangement of the Chemical Atoms in Potassium-Alum and in some of the Bodies which display Tetartohedral Symmetry: William Barlow.—Remarks on Calaverite: Herbert Smith.

ROYAL STATISTICAL SOCIETY, at 5.—The Recent Gold Production of the World: Wynnard Hooper.

WEDNESDAY, JUNE 19.

GEOLOGICAL SOCIETY, at 8.—On Intrusive Tuff-like Igneous Rocks and Breccias in Ireland: J. R. Kilroe and Alexander McHenry.—The Use of a Geological Datum: Beeby Thompson.

ROYAL METEOROLOGICAL SOCIETY, at 4.30.—The Eclipse Cyclone, the Diurnal Cyclones, and the Cyclones and Anticyclones of Temperate Latitudes: H. Helm Clayton.—The Seismograph as a Sensitive Barometer: F. Napier Denison.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Examination of the Abbe Diffraction Theory of the Microscope: J. W. Gordon.

THURSDAY, JUNE 20.

ROYAL SOCIETY, at 4.30.

LINNEAN SOCIETY, at 8.—On the Freshwater Algæ of Ceylon: W. West and G. S. West.—On Coprophilous Fungi: George Massee and E. Salmon.—Revision of the Genus Hypericophyllum, Steetz, with Notes on certain Genera with which it has been confused: N. E. Brown.

CHEMICAL SOCIETY, at 8.—Ballot for the Election of Fellows.—The Direct Union of Carbon and Hydrogen, Part II.: W. A. Bone and D. S. Jerdan. —Ammonium and other Imidosulphites: E. Divers and M. Ogawa.—Nitrilosulphates: E. Divers and T. Haga.—The Decomposition of Hydrocarbons at High Temperatures: W. A. Bone and D. S Jerdan.—The Sugars from Cellulose: H. J. H. Fenton.—On a Theory of Chemical Combination: G. Martin.—On the Occurrence of Paraffins in the Leaf of Tobacco: Dr. T. E. Thorpe, C.B., F.R.S., and John Holmes.—Studies in the Camphane Series, Part IV.: M. O. Forster.—On the Decomposition of Carbon Dioxide, when submitted to Electric Discharge at Low Pressures: Dr. J. N. Collie, F.R.S.—Two New Substances in Lemon Oil: H. E. Burgess.

CHARLES ST. JOHN.

Charles St. John's Note Books, 1846—1853, *Invererne, Nairn, Elgin*. Edited by Admiral H. C. St. John. Pp. 119. (Edinburgh: D. Douglas, 1901.) Price 7s. 6d. net.

TO many an elderly man, among whose most cherished possessions in bygone days was a well-thumbed copy of "Wild Sports in the Highlands" and who now from "life's passionless stage" looks fondly back on the imaginations of youth, "St. John" is still a magic name, awakening, like Campbell's wild flowers, forgotten affections. It brings with it a whiff of the smell of fresh trout frizzling in the mountain sheiling, blue with peat smoke, and calls up visions of misty moors and tumbling rivers, of "muckle harts," wild cats and martens, and

"Sweet little islands twice seen in their lakes,"

gardens of the Hesperides of boyish dreams.

The sportsman-naturalist was a great-great-nephew of the namesake to whom Pope dedicated his "Essay on Man," the first Lord Bolingbroke, and began life as a clerk in the Treasury. A single legend only relating to him survives in Whitehall. A warrant of some importance was wanted, and St. John's chief, remembering that not long before it had been given to him to copy, asked him for it.

The warrant was not forthcoming, and St. John, pressed to find it, with a slight stutter, not impossibly increased by a little nervousness, apologised: "I put it into the fire because it b-b-bored me."

The story may be mythical. But as, according to his own account, he "gave notice to quit to prevent a reversal of the process," it is perhaps not uncharitable to assume that he was one of His Majesty's indifferent bargains.

On leaving the Treasury he retired to a shooting property in the north of Scotland, lent him by a cousin, and shortly afterwards married a Scotch lady blessed with enough of this world's goods to enable him to enjoy to the full a life of busy idleness among red deer and salmon.

It was to a chance acquaintance with Mr. Cosmo Innes, then Sheriff of Moray, and an occasional contributor to the *Quarterly Review*, that three generations of boys are mainly indebted for "Natural History and Sport in Moray" and the yet more fascinating "Wild Sports," which has run through at least seven editions. Mr. Innes was spending an autumn holiday on a property adjoining the shooting over which St. John was privileged to wander with rod and gun. He had wounded a brace of partridges and had followed them from the island in the Findhorn where he found them to a turnip field on the opposite bank, and was looking for them when "a tall, gentlemanly man" with a poodle "with a Mephistopheles face," got over the fence and offered to find the birds which he had marked down.

Mr. Innes called in his pointers and the poodle, "with a series of curious jumps on all fours and pauses between to listen," made short work of the birds—and with this introduction a close friendship sprang up between the two men.

It was a few years later, when a day's cover shooting had been spoilt by a Highland downpour, and St. John, wrapped in a coat of sealskin of his own killing, had whiled away a long wet drive home with stories of sport and of the ways of birds and beasts he had watched, that Mr. Innes first suggested the idea that he should publish his experiences.

St. John was modest, and at first scouted the notion that he could write anything worth printing, but he mentioned "some old journals" which might, if ever the attempt were made, be useful.

The book named above contains these journals, which are now published for the first time in the form in which they were originally written, by the writer's son, Admiral St. John.

The cream of the notes was skimmed long ago for the two books which established St. John's fame, and though well worth printing, their chief interest, for those at least who are familiar with them, now lies, perhaps, in the light thrown on the secret of the fascination which—in spite of the amiable egotism which is apt at times to jar a little—those books possess.

Like White of Selborne and, on a broader canvas, Shakespeare, St. John drew direct from nature.

From a hundred pages, in almost every one of which are texts from which a naturalist might preach a sermon, it is not easy to make selections. But one or two little touches, taken almost at random, are enough to illustrate the breezy freshness of his notes.

"The tracks (of otters) which we see," he writes, "are almost invariably going up the river, showing that the animal keeps the course of the stream in her downward course; but, on coming up, frequently leaves the water to go a few yards along the bank."

Fine swimmer as she is the otter is not a salmon, above all such considerations as up stream and down stream. Again, at the same opening (p. 82),

"The bill of the oyster catcher (unlike the highly sensitive bills of ducks, woodcock and curlews, which patter or bore in the mud for small worms, &c., described a few lines earlier) is as hard as ivory at the tip, the bird using it more for breaking open shell-fish than for digging in the mud."

To give only two more quotations (pp. 74 and 86),

"Wild cats are brindled grey, and I have observed that domestic cats of that colour are more inclined to take to the woods and hunt for themselves than others."

"It blew a hurricane to-day from the W.N.W., with cold showers. . . . I saw a seagull caught by the wind in the air and turned over five or six times before it could recover its balance and get its head to windward."

Admiral St. John, before publishing his father's notes, visited again the scenes of his childhood, and has recorded his impressions in a short preface, "Moray Revisited."

Here, too, as everywhere else in the book, is food for thought for a naturalist.

Stone walls had given place to wire fences; but just where six and thirty years before, in 1851, he had found the nest of a "shoveller," a bird "not common in the locality," a shoveller with a brood of five "swam out of the tall rushes into the open water" as he walked down the river. What is the secret of the lasting attraction of certain particular spots for certain birds? The little brown-headed gulls crowd their nests, very inconveniently close together as it seems to ignorant human beings, in hundreds at one small corner only of a roomy island in Scoulton Mere, and Sheerwaters collect to breed in one only of the hundred and fifty islands of the Scilly archipelago. Guillemots, identified by peculiar egg markings, lay year after year, as Yorkshire cliff climbers agree, "within half an inch" of the same spot on the same narrow ledge.

"Water ouzels," writes St. John (p. 55), "come to the burns near the sea about the beginning of October. The same stones are occupied year after year by these birds."

In a Norfolk cover well known to the present writer, if there was a woodcock in the neighbourhood one was almost always to be found under one particular laurel bush.

Surroundings may completely change without breaking the charm. Thickknees love open spaces, and as a rule nest nowhere else. But Prof. Newton, in the article on migration in his "Dictionary of Birds," tells of their eggs laid in a thick Suffolk cover, in the precise spot where years before, when the ground was still an unplanted heath, birds of the species had been accustomed to breed.

The only thing to be objected to in an otherwise altogether charming book is the paper on which it is printed, which is abominable.

The dazzling glaze which makes reading by candlelight a pain instead of a pleasure is too high a price to pay even for St. John's spirited and witty pen and ink sketches.

If the use of the highly pressed and metallically polished papers which, since the invention of "process blocks," have become fashionable in illustrated magazines is carried much farther—the danger is very real and serious—the eyes of the rising generation will fail them long before their time.

There is something pathetic in the thought of the number of men, younger sons of country gentlemen and sons of officers, clergymen and professional men, born with the deepest-seated of aboriginal instincts—the love of sport—ingrained in their natures and brought up among birds' nests and sticklebacks, who find themselves, during the best years of their life, cut off from all that is most congenial to them and their manhood slipping from them in the close atmosphere of towns.

A writer who, like Charles St. John, can while them away from cramping surroundings and keep alive for a little longer the ever-receding dream of the good time to come some day, is not a man who has lived in vain.

T. Digby Pigott.

EXERCISES IN HYGIENE.

The Science of Hygiene: a Text-book of Laboratory Practice. By Walter C. C. Pakes, D.Ph. (Camb.), F.C.S. Pp. xv + 380. (London: Methuen and Co., 1900.)

"HITHERTO there has appeared no single text-book dealing with all the practical laboratory work which is now required from the candidate for the Diploma in Public Health." So the author writes in his preface, and the work under review is the result of his attempt to remedy what he considers to be "a great disadvantage."

When it is pointed out that in this manual some five subjects are dealt with, each of which has furnished the subject-matter of well-known text-books of similar bulk to the present volume, it is evident that Mr. Pakes's effort must partake somewhat of the nature of a cram book.

"The Science of Hygiene," we would point out, is far too pretentious a title for a small manual which at the most affords the student an incomplete digest of a very extensive branch of study. The inadequacy of treatment would be sufficiently apparent if the different kinds of subject-matter were dealt with in good proportion, but this is not so, for we find the difficult subject of vital statistics disposed of in nineteen pages, ten of which are devoted to the construction of a life table, with the result that no mention is made of one of the most important matters dealt with in vital statistics, namely, the rate of infantile mortality; the subject of physics is dismissed without any mention being made of the siphon or of the common pump, the principles of which should certainly be understood by the public health student; and the great and important matter of the chemical examination of food is dealt with in twenty-eight pages. On the other hand, the part of the work dealing with microscopy covers eighty-nine pages and is by far the most complete and best part of the book.

The work is divided into five parts. Part 1 gives an outline of bacteriology; the brief directions here given are generally sufficient if the worker has the advantage of a teacher at hand when he attempts to put them into practice, otherwise he will frequently find them insufficient. Part 2 deals with microscopy; the illustrations are for the most part good, but the representations of the starches are crude and unsatisfactory. No drawing is given of Cyclops or of Gammarus Pulex, two organisms of far more common occurrence than several of those dealt with by the writer.

In mounting the starches for microscopical examination the student is told to use a "sterilised loop" to moisten the starch with, and a further instance of carelessness is the fact that pages illustrating water sediments are headed "Internal Parasites."

Part 3, which deals with chemistry, also contains blemishes. With reference to the physical characters of water it is said that "if there is any yellowish or brownish colour there will be some suspicion of sewage contamination, unless the water happens to have been collected from a peaty soil." We should have been more disposed to warn the student that it is very rare indeed for sewage contamination, even when it is very considerable, to colour water; iron, on the other hand, is one of the more common causes of such coloration.

In the estimation of chlorides the red precipitate of chromate of silver is described as "brown." The method described for the "estimation of calcium" will include magnesium; and the "estimation of magnesium," when performed in accordance with the directions given, will lead to a very serious under-estimation.

Although the author does not offer "more than a few hints to enable those who are not adepts to avoid the many pitfalls which await them," his remarks upon the interpretation of the results of the analyses of water are faulty in places and would not be acceptable to those who are most *au courant* with this subject. There are many indefinite statements such as the following: "it may happen that a particular geological stratum contains a considerable excess of chlorine," "some geological strata contain nitrates to some considerable degree," "speaking as a rule to which there are of course notable exceptions, drinking water ought not to contain more than 0·5 part per 100,000 of nitric nitrogen."

It is said that a good deep well water often does not absorb more oxygen from the permanganate solution (in four hours at 27° C.) than 0·001 grm. per 100,000. Surely such deep well waters must be very exceptional.

A sample of upland surface water is given with 0·07 of free ammonia, 0·2 of albuminoid ammonia and 0·12 of oxygen absorbed, and with total solids amounting to 2·8 in parts per 100,000, and one of subsoil water with free ammonia 0·12, albuminoid ammonia 0·033, and oxygen absorbed 0·52, without any indication of the fact that these waters are grossly polluted.

Part 3 also deals with the analyses of sewage, sewage effluents and food. In examining sewage, the student is advised that it often happens when 10 or 20 c.c. of sewage are added to 500 c.c. of ammonia free water, that twelve or fourteen Nessler glasses of distillate are collected before the yield of albuminoid ammonia ceases. This is surely a singular experience. Working at such dilutions and under the directions given by the author, it would be extremely rare that more than five or six Nessler glasses would be required; moreover, fourteen Nessler glasses would hold 700 cubic centimetres of distillate, and how is the student to collect this from only some 500 cubic centimetres of liquid in the boiling flask?

On the subject of food analysis we are informed that analysts of repute obtain the specific gravity of milk by weighing with the specific gravity bottle. If this is so, surely there must be few analysts of repute in this country. The average amount of water in butter is put at 8·55 per cent., which is too low; and it is stated that no butter should be condemned as adulterated with water unless it contains less than 80 per cent. of fat; whereas the limit of water accepted by the Society of Public Analysts is 16 per cent. It is said that "in a normal sample of bread there is as much alum as silica," and that "the weight of silica found must therefore be deducted from the amount of alum found, and any excess will represent added alum." As a matter of fact alum is never found in pure bread, nor is it correct to state that there is as much alumina as silica in normal bread.

That the alcohol of wine and beer is determined exactly as in the case of spirits is a bald statement the insufficiency of which will be manifest to the student when, for instance, he first essays an estimation of the alcohol in beer. Doubtless by a printer's error "the Sinaitic Peninsular" is referred to on p. 152, while the atomic weight of silver is given as 107·7 on p. 191, and as 108·0 in the appendix.

It must be said, then, that the volume is on the whole an unsatisfactory one, in which most of the subjects are dealt with, not only inadequately, but sometimes faultily, owing to the attempt to compress too much matter into too small a space.

The subjects of bacteriology, public health, chemical work, physics and vital statistics have, as a matter of fact, all been dealt with in practical manuals in such a manner that the serious student will not find much use for the book under review.

PUBLIC WATER-SUPPLIES.

Public Water-Supplies: Requirements, Resources, and the Construction of Works. By F. E. Turneaure, C.E., and H. L. Russell, Ph.D. Pp. xiv+746. (New York: John Wiley and Sons, 1901. London: Chapman and Hall, Ltd.)

WATER-SUPPLY is unquestionably one of the most important branches of civil engineering in the present day, owing to the widespread nature of the demands for it, the great value attached to a pure supply, resulting from the progress of sanitary science, and the increasing difficulty, in populous countries, of obtaining an unpolluted and adequate supply. This book has been prepared with the object of supplying the needs of teachers and students in technical schools; and the greater portion of it is based on the experience of the first-named author in teaching the subject for many years, which forms one branch of his courses of lectures in the University of Wisconsin. A novel feature in this volume is the conjunction of an engineer and a chemist in its production, thereby enabling the engineering and bacteriological aspects of the question to be dealt with respectively by very competent experts; whilst a chapter on pumping machinery is contributed by another engineer. Fundamental principles have been given more prominence than details of construction, though these latter have been largely made use of to illustrate the principles involved and differences in the conditions, and a considerable space has been devoted to the quality and purification of water-supplies, constituting such important considerations from a sanitary point of view, and also to the questions connected with ground-water. The comprehensive scope of the book, and its exhaustive, though concise, treatment of the subject are most effectively illustrated by a reference to the headings of the twenty-nine chapters into which the book is divided.

The subject is opened by an introductory chapter giving a very brief historical sketch, from the earliest times, of the development of water-supplies, and a statement of the value and importance of a public water-supply for domestic, commercial and public uses. The book is then divided into two parts, the first dealing with "Requirements and Resources," and the second with "The Construction of Water-Works," in nine and nineteen chapters respectively. The first part is subdivided into two sections, with the respective headings, "Quantity of Water Required: Sources of Supply," and "Quality of Water-Supplies," occupying six and three chapters respectively. The first section comprises the quantity of water required, sources of supply, rainfall, evaporation and percolation, flow of streams, and ground-water; whilst the second section deals with the examination of water-supplies, the quality of water, and communicable diseases and water-supplies. The second part of the book, which is devoted to construction, after two introductory chapters dealing with generalities pertaining water-works construction and hydraulics, is subdivided into three sections, treating successively of works for the collection, purification and distribution of water, in six, five and six chapters respectively. The works for the collection of water comprise river and canal intakes, the collection of ground-water, impounding reservoirs, earthen dams, masonry dams, and timber, steel, and loose-rock dams; the section relating to works for the purification of water includes the objects and methods of purification, sedimentation, sand filtration, mechanical filtration and miscellaneous purification processes; and the section dealing with the distribution of water describes systems of pipes for conveying water, conduits and pipe-lines, pumping machinery, distributing and equalising reservoirs, the distributing system and operation and maintenance.

From this summary of the contents it will be seen that all the principal problems and works relating to water-supplies are duly considered in succession; whilst in several chapters the careful classification of the subjects is carried a step further, by the consideration of different branches of the subject to which the chapter is devoted, under separate headings; and the purport of every main paragraph is clearly indicated by a black-letter heading. Moreover, the descriptions are illustrated by two hundred and thirty-one figures in the text; and the quest for further information is greatly facilitated by a list at the end of each chapter of the principal publications on the special subject treated of in the chapter. Naturally, on such a subject as masonry dams, for instance, more particulars might be desired than can be compressed into twenty-two pages, especially as a considerable portion of this limited space is occupied by cross sections of notable dams; and in this case the list at the end of the chapter contains fifty-two references to books, pamphlets, and periodicals describing masonry dams, and six references in addition to failures of these dams; whilst at the end of the chapter on earthen dams there are twenty-seven references to descriptions of such dams, and eleven to their failures. The book, indeed, dwells rather upon general principles and problems than on descriptions of works, except in smaller print by way of illustration, and reliance is placed mainly on the consultation of the publications given in the list for information about details of works. A sound groundwork is presented to the student in a concise form, with reference to the considerations affecting the sources and quality of water, and the nature of the works carried out for the collection, purification, and distribution of water-supplies; and it is expected that he will add to his knowledge thus acquired by the aid of the authorities indicated, and the teachings of experience. This volume, moreover, though specially valuable to students, should also prove useful to experienced engineers, owing to the excellent classification of subjects, the amount of information collected within its pages, and the lists of publications on the various subjects; and whilst engineers will derive special benefit from the full chemical consideration of the quality of water, the diseases transmissible by it, and its purification, chemists interested in water-supplies may gain some advantage from the clear and concise explanations given of the engineering problems and works relating to water-supply.

OUR BOOK SHELF.

Leitfaden der Wetterkunde. Gemeinverständlich bearbeitet. Von Dr. R. Börnstein, Professor an der Königl. landwirthschaftlichen Hochschule zu Berlin. Pp. viii+181. (Braunschweig: Vieweg und Sohn, 1901.)

IT is one of the peculiarities of foreign countries that they have professors of meteorology in their universities and departmental colleges, and the book before us reminds us of that fact. It is a professor's book. It gives a survey of the present state of knowledge of the subject in a form suitable for presentation to a class of intelligent and educated students. The arrangement of the text is systematic and methodical, not historical. It begins with the composition of the atmosphere, and then deals with the elements of climate, namely, temperature, moisture, cloud and precipitation. Then it passes on to consider pressure and its relation to wind and weather, and concludes with an account of the weather services of different countries. It is "gemeinverständlich" in the sense that the special application of mathematics to meteorology is not treated in detail. Instruments are referred to and described, but the details of the process of observation and instructions for observers are not considered.

Within the limits indicated the work is quite successful. The most recent developments of the science are appropriately referred to. The portions dealing with thunderstorms and with weather types are especially satisfactory sections, and all the different parts are effective and concise. The more experienced students of the subject will find the references to original sources of information collected together at the end of the book especially useful. They form a short but comprehensive bibliography of the most important recent work on meteorology. They follow the arrangement of the text, but the excellent alphabetical index to the book makes it easy to look out a reference either to a subject or an author. One misses from the index the names of some prominent American meteorologists, and there are several departments of the science which are only lightly treated; but, as already stated, the book is a professor's presentation of the subject, and is not intended to be exhaustive.

The classification of clouds is the international one, under which clouds of certain types are assigned to certain limits of height. The nine plates of cloud forms are excellent reproductions from the International Cloud Atlas. In other respects also the book is well illustrated, and the print and binding are good.

Myths of Greece explained and dated. An Embalmed History from Uranus to Perseus, including the Eleusinian Mysteries and the Olympic Games. By George St. Clair. 2 vols. Pp. 796. (London: Williams and Norgate, 1901.) Price 16s.

WE do not understand what Mr. St. Clair means by an "embalmed history," and we do not think that the work which he calls by this strange title will be of the least use either to archæologists or ethnologists. Mr. St. Clair starts with the preconceived notion that all myths are of astronomical origin, and argues on the basis of this preconception, *e.g.*, p. 38, "The voyage of the Argonauts was an astronomic quest, as we must surely recognise as soon as we learn that the golden fleece which they sought belonged to the Ram of the Zodiac" (!) The rest of the book is mostly in this strain. The author cannot prove Hera, Leto, Artemis, Hades, Hephaistos or Dionysos to be astronomical, so calmly says (p. 37) "The shifting of pole and equinox and the sponging-out of constellations—which may have been required by calendar-reforms—have made the mythology to appear less astronomical than it was. . . . Most likely many of the Greek divinities may still be found in the sky, under some alias or disguise." And so forth.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Does Chemical Transformation Influence Weight?

CAREFUL experiments by Heydweiller, published in the last number of Drude's *Annalen* (vol. v. p. 394), lead their author to the conclusion that in certain cases chemical action is accompanied by a minute, but real, alteration of weight. The chemical actions here involved must be regarded as very mild ones, *e.g.* the mere dissolution of cupric sulphate in water, or the substitution of iron for copper in that salt.

The evidence for the reality of these changes, which amount to 0·2 or 0·3 mg., and are accordingly well within the powers of a good balance to demonstrate, will need careful scrutiny; but it may not be premature to consider what is involved in the acceptance of it. The first question which arises is—does the *mass* change as well as the *weight*? The affirmative answer, although perhaps not absolutely inconsistent with any well ascertained fact, will certainly be admitted with reluctance. The alternative—that mass and weight are not always in proportion—involves the conclusion, in contradiction to Newton, that the length of the seconds' pendulum at a given place depends upon the material of which the bob is composed. Newton's experiment was repeated by Bessel, who tried a number of metals, including gold, silver, lead, iron, zinc, as well as marble and quartz, and whose conclusion was that the length of the seconds' pendulum formed of these materials did not vary by one part in 60,000. At the present day it might be possible to improve even upon Bessel, or at any rate to include more diverse substances in the comparisons; but in any case the accuracy obtainable would fall much short of that realised in weighings.

As regards Heydweiller's experiments themselves, there is one suggestion which I may make as to a possible source of error. Is the chemical action sufficiently in abeyance at the time of the first weighing? If there is copper sulphate in one branch of an inverted U and water in the other, the equilibrium can hardly be complete. The water all the time tends to distil over into the salt, and any such distillation must be attended by thermal effects which would interfere with the accuracy of the weighing. RAYLEIGH.

June 11.

The National Antarctic Expedition.

IN consequence of a cable received yesterday from London, telling me that the instructions for the conduct of the Nationa Antarctic Expedition that had been passed by the Joint Committee of the Royal Society and the Royal Geographical Society have been greatly altered, I feel it my duty to resign the post of head of the civilian scientific staff of the expedition, which I had provisionally accepted. The organisation of the expedition now passed leaves the head of the civilian scientific staff nominally responsible for most of the scientific work of the expedition, but gives him no power to secure the performance of the scientific part of the programme.

The responsibility for my withdrawal at so late a date rests with those who have delayed until now the settlement of the programme and organisation of the expedition, which should both have been decided, as I understood they had been, before the ship and most of the equipment had been ordered.

I trust the protest of my withdrawal will secure to my successor more favourable conditions of work than the altered instructions would have given me.

University, Melbourne, May 4. J. W. GREGORY.

The Settlement of Solid Matter in Fresh and Salt Water.

SINCE the publication of the report of Mr. Slidell[1] on the deposits of the Mississippi delta, containing the remarkable statement that while the deposit contained in the river water of the Mississippi took from ten to fourteen days to settle, with solutions of salt, sea water or sulphuric acid the water became limpid in from fourteen to eighteen hours, it has generally been taken as an accepted fact that alluvial matter settles more rapidly in salt than in fresh water. Sir Archibald Geikie, in his "Text-book of Geology," endorses this theory; and in a recent article in the *American Engineering Magazine* on the transportation of solid matter by rivers, Mr. Starling, one of the Government river engineers, states that a small quantity of salt or other foreign material dissolved in water will diminish the suspending power and increase the rapidity of subsidence to a marked degree, sometimes even many hundred-fold.

On the face of it the result naturally expected would be, that as sea water is of greater specific gravity than fresh water, and more viscous, the grains of solid matter would sink more slowly in salt than in fresh water. The very great distance over which solid matter brought down by rivers remains in suspension after reaching the sea, extending from six miles from the mouth of the Rhone to thirty-five from the outlet of the Nile, up to 300 miles over which the sea water is stated to be discoloured by the effluent of the Amazon, appears to indicate that salt water is capable of retaining solid matter in suspension for a longer time than fresh water.

Experiments made by Mr. Vernon Harcourt with alluvial matter placed in suspension in sea water and fresh water, and in solutions containing different strengths of salt and other foreign material, although not of a conclusive character, show that there is little difference between the rate of deposit in sea or in fresh water. Of samples from different estuaries which were allowed to settle in sea water and pond water respectively, the particles of the former took about 9 per cent. more time to subside than the latter. The general conclusion he arrived at was that, though sea water promotes the deposit of "very light clayey matter contained in river silt under favourable conditions, there are no grounds for regarding it as exercising the very preponderating influence on the formation of deltas attributed to it by geologists."[1]

The writer some time ago investigated this subject in connection with researches he was then making as to alluvial deposits in estuaries, and has again more recently conducted a series of experiments the mean results of which are given in the following table:—

Table Showing Rate of Settlement of Solid Matter in Fresh and Salt Water.

No.	Number of grains to a lineal inch	Material	Time taken to settle: Fresh	Time taken to settle: Salt	Water clear: Fresh	Water clear: Salt	
			m. s.	m. s.	h. m.	h. m.	
1	100	Sand	0 10	—	—	—	Water not discoloured
2	200	do.	0 25	—	—	—	do.
3	—	Whiting ...	12 0	—	0 30	—	
4	—	Plaster of Paris	5 0	—	0 10	—	
5	300	Warp, Trent	0 43	0 45	0 1	0 1	Water scarcely discoloured
6	1400	Fine Warp, Dutch River	12 0	15 0	3 30	22 0	
7	500	Silt, Salt Marsh	2 0	2 0	0 6	0 9	
8	1000	Warp, do. ...	8 0	9 0	1 0	0 33	
9	2000	Alluvium, Boston Dock ...	33 0	28 0	7 0	1 30	
10	600	do., R. Parrett	4 0	2 40	0 15	0 18	
11	1500	do., Tilbury Bsn.	18 0	18 0	10 0	9 0	
12	1600	Brick Clay ...	17 0	15 0	1 30	1 9	

It will be seen from this table that the rate of deposit depends on the minuteness of the particles in suspension, and varies nearly in proportion as the square of the diameter of these.

With sand and silt there was practically no difference in the rate of settlement in fresh as compared with salt water. When the particles of the solid matter were very fine, as in the case of what is generally known as mud or ooze, the rate of settlement was slightly more rapid in salt than in fresh water; but there was nothing to justify the conclusion arrived at by Mr. Slidell.

All the material was first screened through a sieve having ninety meshes to the lineal inch.

The proportion by weight of solid matter to water was that which was found to exist on the average of fourteen large rivers

[1] Report on the Mississippi River by Humphreys and Abbott, 1861.

[1] "Investigation on the Action of Sea Water in Accelerating the Deposit of River Silt" (*Min. Proc. Inst. C.E.*, vol. cxlii.).

when in flood, or ·79 lb. to a cubic foot equal to 1/80th part in weight of the water in the tubes.

Both sea water and water saturated with ordinary salt were tried, the latter in the proportion of one pound of salt to a cubic foot. There was no appreciable difference between these.

The samples were placed in glass test-tubes 1 foot long and ½ inch in diameter, filled with clean water up to the ten inch mark.

The material was well shaken and incorporated with the water, and the time given for settling is that taken by the particles to settle through 10 inches and become visible in a solid form at the bottom of the tube, and when no more particles could be discerned as settling when the tube was held up to the light.

The column "water clear" is that in which the water in the tube had become sufficiently transparent for black marks on a white ground to be discerned through it.

Practically all solid matter had settled in the time given in the first column. The quantity deposited between the interval of "settling" and "clear" was almost inappreciable, but still sufficient to keep the water discoloured. With the specimens containing the coarser material the water became bright again in the time given in the second column, but with the very fine material intervals varying from two to three hours up to as many days elapsed before the water became as bright as it was before the solid matter was added, partly depending on the fineness of the material, but due more to the staining quality of some of the ingredients contained in the sample. Thus the material taken from Tilbury Dock Basin turned the water a black colour which took some time to clear. The salt water took much longer to become bright again than the fresh.

Samples were selected as fairly representing the material brought down in suspension by rivers, or eroded from the sea cliffs, and deposited either in the form of salt marshes or transported to the bed of the sea.

Thus numbers 1 and 2 represent the sand found on the foreshores of the sea coast and covered at every tide; 3 and 4, material derived from chalk cliffs; 5 and 6, the material in suspension in the rivers Ouse and Trent, of which the Warp lands bordering on those rivers are composed, 5 being the material first deposited and near the river, and 6 that further away where the water remains quiescent for some time; 7 and 8 represent the material of which salt marshes are composed, 7 being the silt deposited on the sand, and on which, when it rises to about neap tide level, 6·68 above ordnance datum, samphire begins to grow, 8 the finer warp deposited from about the level of mean high water to that of ordinary spring tides, or 10·21 to 13·34 above ordnance datum, on which salt water grass grows; 9 is alluvial matter chiefly derived from the erosion of clay banks, brought up by the tides and deposited in Boston Dock, whence it was dredged, elevated from the barges and discharged with a current of water on to low land, the sample being taken at the part furthest away from the place of deposit; 10 was taken from the "batches" on the banks of the river Parrett at about half-tide level of spring tides, or 13·67 above ordnance datum, where the finest part of the alluvium in the river settles and which is collected for making bath bricks; 11 was taken from Tilbury Dock Basin on the Thames when the water was being stirred up by the eroding pumps; 12 is from clay used for brick making; 30 per cent. of the particles of this material were from 1/800th to 1/1000th inch in diameter and the remainder smaller than this, the average size being 1/1600 of an inch.

W. H. WHEELER.

The Subjective Lowering of Pitch.

IF the subjective effect described by Mr. E. Hurren Harding (*ante*, p. 103) is of general occurrence, it is contrary to what one might expect from the observation of singers.

It is well known that persons with a good ear may sing flat, being unconscious of the defect, though they would notice it immediately in other singers. From this it seems that the singer's voice sounds *higher* to himself than to others, and yet it is *louder* to him than to any one else. Sharp-singing, on the other hand, is regarded as more indicative of a defective ear.

I have no large tuning-forks at hand, but with ordinary forks and the sound-board of a piano I find that, on bringing the ear close to the source of sound, the sense of pitch is not altered, though the elements of noise are added to the sound; and these elements consist mostly of vibrations of lower pitch, presumably the proper notes of parts of the auditory apparatus.

In connection with this subject it may be noted that, owing to the structure of the cochlea, vibrations of small amplitude affect chiefly the lower part of its spiral; and that as the amplitude increases (independently of pitch?) the concussion reaches further up the spiral, where the fibres of the basilar membrane are longer than in the lower part, and therefore more responsive to slower vibrations. F. J. ALLEN.

Malvern, June 9.

WITH reference to Mr. Harding's letter (p. 103), it would be interesting to know whether the effect he has observed with the voice, with tuning-forks and with organ pipes can also be obtained from a siren. G. W. HEMMING.

YES; such effect can be obtained from a siren. If a siren be so rotated as to give a note approximating to middle C, the note appears flattened when the ear is placed close to the instrument, such flattening being estimated by different observers (at different times) as from a semitone to a whole tone.

Normal College, Bangor. E. HURREN HARDING.

THE NATIONAL ANTARCTIC EXPEDITION.

NO answer, so far as we are aware, has appeared to Prof. Poulton's letter to the Fellows of the Royal Society on Prof. Gregory's resignation of the leadership of the scientific staff of the Antarctic expedition (of which we published a copy on May 23). We are therefore forced to conclude that the representatives of this Society on the Joint Committee are content (to use our own words) to let judgment go by default, and admit Prof. Poulton's statements to be substantially correct. Since that date, according to a second letter which we published last week, rumours have been circulated that the real cause of Prof. Gregory's resignation was not that which had been publicly stated, but domestic considerations. The dates given to Prof. Poulton's statements and extracts from letters written by Prof. Gregory (which documents we have been allowed to examine) show these rumours to be baseless, and how they have arisen is no less a mystery than that alteration in the minutes of a resolution passed by the Joint Committee on February 14, 1900, mentioned in Prof. Poulton's former letter. Prof. Gregory's position has been consistent and definite throughout. He accepted the offer of the post on certain conditions, which he believed himself (not unreasonably, in our opinion) to have made clear. On returning to England last December he found the situation had been altered. Though not liking the changes he decided to accept them, and naturally supposed when he left England last February that the arrangement, concluded the day before he sailed, would be final. On receipt of a cable message that it had been further modified (by the acceptance, in substance, of Mr. Darwin's proposition), his first impulse, as he states, when the news arrived was to send a telegram announcing his resignation; but, after reflection, he thought it wiser to await the receipt of particulars by letter. Then came the refusal of the Council of the Royal Geographical Society to accept the instructions, thus modified, the appointment of an arbitration committee, as we may call it, and their decision, which virtually endorsed the action of that Society. When Prof. Gregory was informed by telegraph of the last step he at once cabled his resignation. We do not see how he could have done otherwise. There was now, to use his own words, "no guarantee to prevent the scientific work from being subordinated to naval adventure, an object admirable in itself, but not the one for which I understood this expedition to be organised."

Prof. Gregory, some experts have pleaded, is unreasonable in his expectations; the rules of the Service necessitate the complete autocracy of the naval officer in command. We content ourselves with the reply that if this be so it is only one more instance of the deleterious effect of red tape in this country, of which we have just received, in the case of the War Office, so impressive, we may say so humiliating, a lesson. Others may ask: Why could not Prof. Gregory have shown a more trustful spirit and sailed in the *Discovery*, believing all things and hoping all things? There are limits even to faith. Had the commander of the expedition been a man distinctly his senior, already accustomed to scientific voyages, with some experience of polar exploration and those special problems which may be solved by the Antarctic expedition, Prof. Gregory might have ventured to dispense with securities and to feel confident that the interests of science would not be subordinated to the more showy work of adding new capes and islands to the map. But is this the case? The commander of the *Discovery*, we are informed, was, not many months ago, torpedo-lieutenant on a man-of-war, has had no experience in either Arctic or Antarctic seas, is no doubt well versed in those subjects of which a knowledge was demanded by his former post, may possibly be thoroughly competent to direct magnetic observations, but he has not as yet won the slightest reputation as a naturalist, a geologist, or an investigator of glacial problems. The last two qualifications are of exceptional importance in this expedition. They cannot be acquired on the voyage out, even by the help of a tutor; they demand, not only book learning, but also much practical experience. This Prof. Gregory possesses in an exceptional degree. He knows where a search for fossils will be the most hopeful and what will be of most value to palæontologists. He has mastered the literature of glacial questions, and he has studied glaciers themselves, in the Alps, Spitsbergen and elsewhere. He has travelled much, and on his notable expedition to Mount Kenya displayed powers of organisation, calmness in critical circumstances, physical endurance and moral courage which gave him at once a high place among explorers. He has a reputation to lose. Can he be expected to imperil that by absolute surrender to one who is probably his junior and is without experience in the branches of science of which he is a master? As Prof. Gregory truly remarks: "The position gives no power to secure a fair opportunity for work to the man who would have to bear the blame for scientific failure." It was not the position which he had originally consented to accept, it was not that which was agreed upon when he left England last February; so, perceiving that he was no longer supported by those whom he had regarded as representing the interests of science, he promptly withdrew from an untenable position.

The action of those representatives (or rather the majority of them) is inexplicable. They have worked, we hear it said, in the interests of peace. But there are occasions when even peace may be too dearly bought. "There must be give and take," one of them pleaded at a notable crisis. Certainly, but it has been all give on the one side and all take on the other. "The Council of the Royal Geographical Society," it was urged, "were acting within their rights when they rejected the instructions, as modified by their secretary." Certainly, so is one nation doing when it breaks off diplomatic relations with another, and in this way their action should have been regarded by the Council of the Royal Society. That body, or its representatives, seem to have adopted, at least during the present year, "a peace at any price" policy. In consenting to the appointment of a committee of arbitration they meekly accepted a snub, and in designating its members they exposed themselves to defeat. We have the highest respect for their nominees individually, but not one of them is a recognised expert in those branches of science the interests of which were most at stake. The other half of the court consisted of geographers—that is, of men who were really counsel for that side—and yet this court called no scientific experts to plead before it, though this had been virtually promised, but promptly gave its decision. Time would be saved if this practice were imitated in our law courts, but whether justice would be promoted is another question.

It has, however, been asserted that the Royal Geographical Society ought to be allowed a preponderant influence in the organisation of this expedition, because it had provided, directly or indirectly, most of the funds. This difficulty, however, is so obvious that it should have been foreseen at the outset, and the Royal Society have been careful to protect itself from being forced into a false position by inequality of contribution.

But we may go on to ask, does the Royal Geographical Society flatter itself that the Government would have made that grant of 45,000*l*. if its application had not been so energetically and heartily supported by the Royal Society? We venture to be sceptical on this point, and so to affirm that it was the duty of the latter body, at any rate after the rejection of the amended instructions by the Council of the Royal Geographical Society, to have announced that, while wishing all success to the Antarctic expedition, it could no longer be responsible for the guidance of its scientific work or the expenditure of public money. Now it must be content to follow whither the geographers lead. It will receive little honour for any successes, but will have to bear much of the blame if the scientific results are of small value. Its representatives have not afforded, as Prof. Poulton complained, to "the claims of the scientific chief in an expedition undertaken to do scientific work . . . that unflinching, undivided and resolute support" which not only he, but also those who set science above even geographical exploration, had expected and desired.

THE TELEGRAPHONE.

A DESCRIPTION of the telegraphone—the remarkable recording telephone invented by Herr Poulsen—was given in these columns in August last (vol. lxii. p. 371). At that time the instrument was on view at the Paris Exhibition, and though we were able the explain the principle upon which it was designed we could give no detailed description of the actual instrument, nor had we ourselves been able to test its powers. Since then it has been brought to England and has been exhibited at the Royal Society and at other places, where it has deservedly attracted a very large amount of attention. A further description may, therefore, in the circumstances be acceptable.

Herr Poulsen's invention fully deserves to be called one of the most astonishing that have been made of late years. That the delicate vibrations of the human voice could be changed into variations of an electric current and thus be transmitted over a distance and reproduced at the far end came as a surprise to men of science a quarter of a century ago. With no less surprise do we learn today that these telephonic currents, small though they are, can yet be used to create permanent magnetic fields in a steel wire, which will thus be made to serve as a tablet on which to write one's speech. It is not to be wondered at that when first Herr Poulsen's discovery was announced many were incredulous as to its genuineness; the invention is precisely of the kind that one does not believe could be practical until one has actually seen or heard it in operation. That it will have the effect of putting the phonograph on an entirely new basis no one who has heard it can doubt. The speech reproduced by the telegraphone is almost as much superior to that reproduced by the wax cylinder phonograph as are the living pictures of the kinematograph to those of the zoetrope. There is none of the very unpleasant twang inseparable from the ordinary phonograph ; the speech is as clear and distinct as that transmitted through a good telephone.

In Fig. 1 is shown a photograph of one form of the telegraphone, in which the steel wire that is intended to receive the record is wound in a spiral on a drum, this drum being rotated either by a small motor or by hand, as shown. The little magnet which imprints the records on the wire is seen on the front of the drum with the wires leading from it to the transmitting or receiving telephone. The magnet is mounted on a small carriage, which slides on a bar going from right to left of the instrument at the top. At the back, attached to the same carriage, is a small plough, which engages with the steel wire on the drum and thus acts as a guide. When it is desired to speak to the instrument the magnet is started at the right hand side and the plough made to engage with the wire. The drum is then rotated, and as it turns the magnet moves from right to left, the wire passing all the time between its poles. During this motion any words spoken into a telephone connected to the magnet will be recorded as a series of magnetic fields on the wire. When the magnet arrives at the end of the wire the mechanical trip on the left of the instrument lifts the plough off the recording wire and makes it engage with a wire wound in a wide helix, which can be seen at the back; this causes the carriage and magnet to return quickly to the starting point. To reproduce the record the magnet is connected to a telephone receiver and is again made to travel along the spiral ; as the now magnetised wire passes between its poles it sets up currents which reproduce the recorded speech in the receiver.

The record can be left on the wire and used over and over again ; it is not certain how long the record will last, as sufficient time has not yet elapsed to test this point. We heard a song in Danish which had been sung to one of these instruments some months ago, before it was taken away from Copenhagen ; though the song had been repeated a very great number of times it still seemed very distinct, though, being in Danish, we cannot venture to express any opinion on the articulation. If, however, it be desired to wipe out the record, a steady current is passed through the magnet coils as it travels from end to end of the recording wire ; this effectually destroys all the existing record and leaves the wire ready to receive a fresh one. This form of instrument is comparable to the ordinary phonograph in that it can only receive a record of one or two minutes' duration ; but, quite apart from its greater clearness, it is superior to the phonograph because the records can be so easily wiped out and fresh ones made.

Another form of telegraphone is shown in Fig. 2. In this a steel ribbon is used instead of a wire to receive the record. The ribbon is wound on two drums so that it can be unrolled from one on to the other. As it goes from one drum to the other it passes over the poles of the recording magnet, which is connected, as before, with the telephone receiver or transmitter. It is remarkable that although the convolutions of the ribbon when wound on the drums lie closely one above the other, the magnetic fields on one turn do not seem to interfere with those on another. With this arrangement it is easily possible to cut off any length of ribbon holding a particular record which it is desired to preserve.

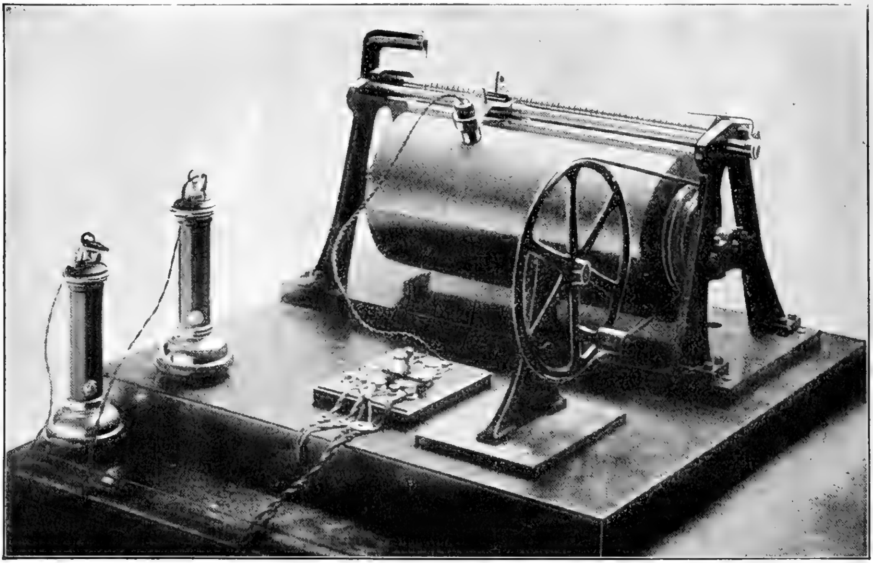

Fig. 1.—Steel Wire Telegraphone (From the *Electrician*.)

A very ingenious apparatus has been devised by which a message may be transmitted simultaneously to any number of stations, an arrangement which should prove very useful for many purposes, for example for Press messages, &c. A diagram of this apparatus is shown in Fig. 3. An endless steel ribbon, R, passes round two pulleys, A and B, driven by a motor. This ribbon, after it leaves the pulley, A, comes to a strong permanent magnet, P, which wipes out any record existing on it. It then comes to a magnet, M, connected with the microphone transmitter, and from this it receives a record of any words spoken. The ribbon, now carrying a record, next comes to a series of magnets, M_1, M_2, M_3 . . . each of which is connected to a different circuit. The message is thus transmitted by the magnets, M_1, M_2 . . . to any number of distant stations at the same, or practically the same, moment. The ribbon after leaving the last magnet comes round again

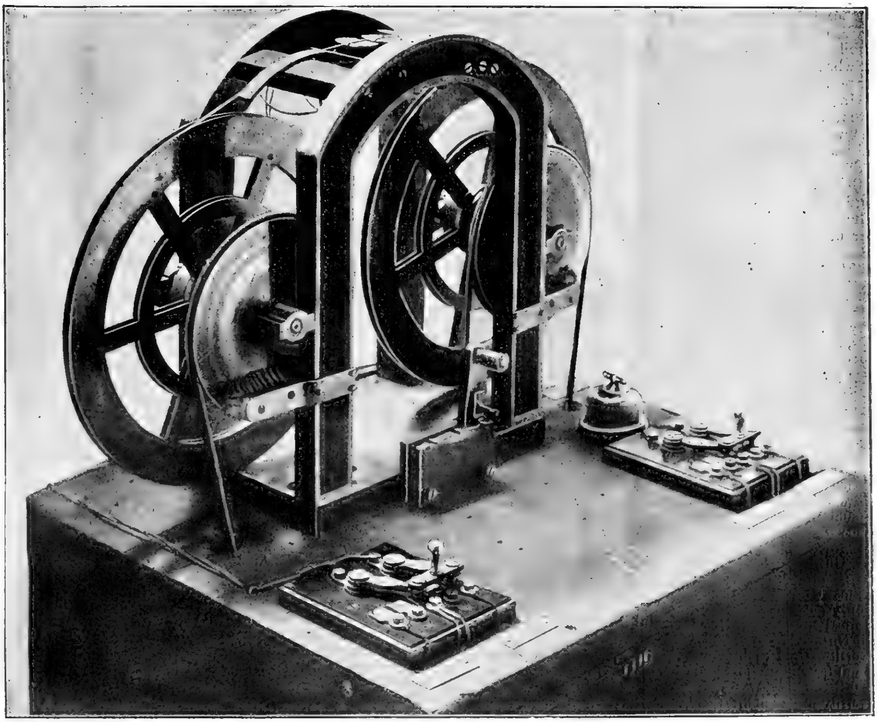

FIG. 2.—Steel Ribbon Telegraphone. (From the *Electrician*.)

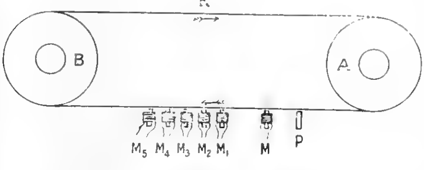

FIG. 3.—Distributing Telegraphone.

in due course to the permanent magnet, P, by which it is cleaned to receive fresh magnetisation; thus messages of any length can be sent by this means.

From this arrangement is derived the telephonic relay to which we referred in our last article. Let the series of magnets M_1, M_2 . . . instead of being connected to distant receiving telephones be connected to a series of recording magnets which are used to produce records on a number of steel tapes. If all these steel tapes be made to repeat their record at the same instant to a single receiving telephone the loudness of the speech will be increased in proportion to the number of ribbons used.

We understand that successful experiments have been carried out on these lines, but that no actual relay has as yet been constructed. It is to be noted that as the energy is derived from the motion of the ribbons, and therefore from the motor used to drive them, there is theoretically no limit to the loudness that could be attained. If Herr Poulsen is really successful in constructing a telephonic relay, as there seems to be every prospect of his being, he will have accomplished a feat of immensely greater importance than the invention of an improved phonograph, or even of a satisfactory recording telephone. So far as this last point is concerned we learn that very successful trials have been carried out in America between Boston and New York. The ordinary telephone lines were used, the telegraphone being substituted for the receiver at one end; a good and clear record of the transmitted speech is said to have been obtained.

THE NINTH JUBILEE OF GLASGOW UNIVERSITY.

THE ninth jubilee of the University of Glasgow was celebrated last week with brilliant ceremony. The proceedings opened on Wednesday with a commemoration service in Glasgow Cathedral, when a sermon was preached by Dr. M'Adam Muir. In the afternoon Principal Story, the Vice-Chancellor, on taking the chair, read the following telegram from the King:—"I remember with what great pleasure I laid the foundation stone of your new buildings in 1866, and I heartily congratulate the University on the celebration of the 450th year of its existence." He then addressed a welcome to the delegates, who subsequently presented addresses from universities, colleges and other learned and public bodies on the Continent, in the United States of America, the British colonies and dependencies, and the United Kingdom.

The foreign institutions represented, in alphabetical order of countries, were as follows:—

Austria-Hungary: Universities of Cracow, Klausenburg, Lemberg, Prague and Vienna. *Belgium:* Free University of Brussels, Royal Academy of Science, Letters and Art, University of Liège, and Catholic University of Louvain. *Finland:* University of Helsingfors. *France:* Universities of Caen, Lille, Lyons, Aix-Marseilles, Montpellier, Paris and Rennes, Academy of Medicine, Institute of France, and Franco-Scottish Society. *Germany:* Universities of Breslau, Göttingen, Heidelberg, Kiel and Leipzig, and Royal Society of Sciences, Göttingen. *Holland:* Royal Academy of Sciences, and University of Utrecht. *Italy:* Universities of Bologna, Padua, Rome and Turin, Royal Academy of Sciences, Bologna, Royal Society of Naples, Italian Society of Science, Royal Academy of Sciences, Turin, and Royal Institute of Science, Letters and Art, Venice. *Japan:* University of Tokio. *Norway:* University of Christiania. *Portugal:* University of Coimbra. *Russia:* Universities of Kieff and Moscow, Imperial Society of Naturalists, and Imperial Military Academy of Medicine. *Spain:* University of Zaragoza. *Sweden:* Universities of Lund and Upsala. *Switzerland:* Universities of Bern, Geneva, Lausanne and Neuchatel. *United States of America:* University of Michigan, Johns Hopkins University, University of California, University of Boston, American Academy of Arts and Sciences, Massachusetts Historical Society, University of Chicago, University of Missouri, North-Western University, Dartmouth College, Cornell University, University of Wisconsin, Yale University, American Oriental Society, Columbia University, New York, Union Theological Seminary, New York, Leland Stanford Junior University, University of Pennsylvania, American Philosophical Society, Historical Society of Pennsylvania, Princeton University, Cooper Medical College, Columbian University, National Academy of Sciences, Smithsonian Institution, Clark University, American Philological Association, Archæological Institute of America, and Smith College.

The institutions in British Colonies and Dependencies represented at the celebration were:—

Australia: Universities of Adelaide, Melbourne and Sydney. *Canada:* Dalhousie University, Queen's College, Kingston, M'Gill University, and the University of Toronto. *India:* Universities of Allahabad, Bombay, Calcutta, Lahore (Punjab University) and Madras, and Asiatic Society of Bengal. *New Zealand:* University College, Auckland.

On the morning of Thursday there was a crowded attendance in the Bute Hall of the University to hear an oration on James Watt by Lord Kelvin, and another by Prof. Smart on Adam Smith, and to see the graduation ceremony at the conclusion of the addresses.

Lord Kelvin described Watt's career and achievements in an address of which the following is an abstract:—

The name of James Watt was famous throughout the whole world, in every part of which his great work had conferred benefits on mankind in continually increasing volume up to the present day. It was fitting that the University of Glasgow, in this celebration of its ninth jubilee, should recollect with pride the privilege it happily exercised 145 years ago of lending a helping hand and giving a workshop within its walls to a young man of no University education, struggling to begin earning a livelihood as a mathematical instrument maker, in whom was then discovered something of the genius destined for such great things in the future. In a note by Watt appended to Prof. Robison's dissertation on steam engines, he said that his attention was first directed in the year 1759 to the subject of steam engines by the late Dr. Robison, then a student in the University of Glasgow and nearly of his own age. He at that time threw out an idea of applying the power of the steam engine to the moving of wheel carriages and to other purposes, but the scheme was not matured, and was soon abandoned. On his going abroad about the year 1761 or 1762, Watt tried some experiments on the force of steam in a Papin's digester, and formed a species of steam engine by fixing upon it a syringe one-third of an inch diameter with a solid piston, and furnished also with a cock to admit the steam from the digester or shut it off at pleasure, as well as to open a communication from the inside of the syringe to the open air, by which the steam contained in the syringe might escape. That single acting, high-pressure syringe engine, made and experimented on by James Watt 140 years ago in his Glasgow College workshop, now in 1901, with the addition of a surface condenser cooled by air to receive the waste steam and a pump to return the water thence to the boiler, constituted the common road motor, which, in the opinion of many good judges, was the most successful of all the different forms tried within the last few years. Watt left Glasgow in 1774 to live in the neighbourhood of Dr. Erasmus Darwin, grandfather of Charles Darwin. But Greenock and the University and City of Glasgow never lost James Watt. The University conferred the honorary degree of LL.D. upon him in 1806. In 1808 he founded the Watt Prize in Glasgow College. He became Fellow of the Royal Society of Edinburgh in 1784, Fellow of the Royal Society of London in 1785, correspondent of the French Academy of Sciences in 1808, one of the eight "Associés Etrangers" of the French Academy of Sciences in 1814. Lord Kelvin did not know if any University in the world ever had a tradesman's workshop and saleshop within its walls, even for the making and selling of mathematical instruments, prior to 1757. But whether the University of Glasgow was or was not unique in its beneficent infraction of usage in this respect, it was certainly unique in being the first British University—perhaps the first University in the world—to have an engineering school and professorship of engineering. This began under Prof. Lewis Gordon about 1843. Glasgow was certainly the first University to have a chemical teaching laboratory for students started by its first professor of chemistry, Thomas Thomson, some time between 1818 and 1830. Glasgow was also certainly the first University to have a physical laboratory for the exercise and instruction of students' experimental work, which grew up with very imperfect appliances between 1846 and 1856. Pioneer though it was in those three departments, it had been outstripped within the last ten or fifteen years by other Universities and colleges in the elaborate buildings and instruments now needed to work effectively for the increase of knowledge by experimental research and the practical instruction of students. But there was no lagging to-day in the resolution to improve to the utmost in all affairs of practical importance, and they almost saw attainment of the further aspirations to excel over all others in the magnificent James Watt Engineering Laboratory of the University of Glasgow to be ready for work before the expected meeting of the Engineering Congress next September. Now, through the magnificently generous kindness of Mr. Andrew Carnegie to the people among whom he has made for himself a summer home in the land of his birth, all the four Scottish Universities could look forward to a largely increased power of benefiting the world by scientific research and by extending their teaching to young people chosen from every class of society as likely to be made better and happier and more useful to our country by University education.

The honorary degrees were afterwards conferred. The list was by far the longest that has ever been submitted at any graduation ceremony at the University. It included 22 Doctors of Divinity and no fewer than 120

Doctors of Laws, including several ladies. This is the first instance of the bestowal by the University of honorary degrees upon ladies.

The new botanical department of the University was opened by Sir Joseph Hooker on Thursday in the presence of a distinguished company. Sir Joseph Hooker prefaced the ceremony with a description of the work done by his father both before and after he became professor of botany in the University in the first quarter of last century. He had not been educated for the medical, or, indeed, any other learned profession. Having inherited ample means and having been from childhood devoted to the study and collection of objects of natural history, he determined to devote his life and his fortune to travel and scientific pursuits. Early in 1820, reduced circumstances requiring him to turn his botanical attainments to material account, he obtained, through the influence of his friend Sir Joseph Banks with George III., the chair of Regius Professor of Botany in this University. It was a bold venture for him to undertake so responsible an office, for he had never lectured, or even attended a course of lectures, and in Glasgow, as in all other Universities in the kingdom, the botanical chair was, and had always been, held by a graduate in medicine. Owing to these disqualifications his appointment was naturally unfavourably viewed by the medical faculty of the University. But he had resources that enabled him to overcome all obstacles—familiarity with his subject, devotion to its study, energy, eloquence, a commanding presence, with urbanity of manners, and, above all, the art of making the student love the science he taught. Continuing, Sir Joseph Hooker said :—

If I were asked what I regarded as of most importance to the student in the manner of my father's teaching I would answer that it taught the art of exact observation and reasoning therefrom, a schooling of inestimable value for the medical man, and one that is given in no other profession, but which ought to come, in this country, as it does in Germany, early in the education of every child. I have met many of my father's pupils abroad, in India and the Colonies, who have told me that these botanical lectures gave them the first ideas they had ever entertained of there being a natural classification of the members of the vegetable kingdom. Then with regard to the results in a botanical point of view, the magnetism of the lecturer and the interest of the subject imbued many of his pupils with a love of science that proved permanent and fruitful. They made observations and collections for their quondam professor in the temperate and tropical climates of both hemispheres, some of them throughout their lives, which have very largely contributed to a knowledge of the flora and vegetable resources of the globe. After twenty years of professorship my father retired, and undertook the directorship of the Royal Gardens, Kew. Since that period great changes have been introduced in the method of botanical teaching in all our Universities, due, on the one hand, to a vastly advanced comprehension of the structure of plants and of the functions of their organs, and, on the other, to a recognition of the fact that the study of the animal and vegetable kingdoms cannot be considered apart. Furthermore, chemistry, physics and greatly improved microscopes are now necessary for the elucidation of the elementary problems of plant life. The instruction in these two sciences (chemistry and physics) has with all others advanced in this University *pari passu* with that of botany, and kept it in the forefront of the educational establishments of the kingdom. The addition of the building in which we are assembled is evidence of the resolve that it shall not relax its efforts to maintain its well-earned position, and with the conviction that the botanical laboratory will prove an invaluable aid to research under the ægis of its distinguished director, I now, under his authority, declare it open.

The official celebration of the jubilee was brought to a close on Friday, when an oration on William Hunter, by Prof. Young, was read by Prof. Bower in the Bute Hall.

NOTES.

THE late Prof. G. F. Fitzgerald was so highly esteemed in the world of science that a movement to establish a memorial of his greatness will certainly meet with ready and liberal support. It is proposed to found a "Fitzgerald Research Scholarship," to be awarded annually at Trinity College, Dublin; and a large and influential committee of leaders of science at home and abroad has been formed to obtain funds for this purpose. The object is one which would have had the entire approval of Prof. Fitzgerald, whose chief care was the encouragement of experimental research in the laboratories entrusted to his guidance at Trinity College. The scholarship would be attached to the department of experimental physics in the College, and would enable promising students to pursue investigations which, for want of means of immediate support, might otherwise have to be relinquished. Prof. Fitzgerald's marvellous faculties and noble character are so well known and appreciated among scientific men that it is almost unnecessary to urge the claims of the object to their attention. We have confidence that the response to the appeal for funds will be sufficient to provide an adequate endowment for the scholarship it is desired to establish. Subscriptions should be sent to one of the honorary treasurers, Prof. D. J. Cunningham, F.R.S., or Dr. H. H. Dixon, Trinity College, Dublin.

A COMMITTEE has recently been appointed by the Institution of Civil Engineers, with the support of the Institutions of Mechanical Engineers and Naval Architects and of the Iron and Steel Institute, to consider the advisability of standardising the various kinds of iron and steel sections, and, if found advisable, then to consider and report as to the steps which should be taken to carry such standardisation into practice. The committee is composed as follows:—Mr. James Mansergh, Sir Benjamin Baker, K.C.M.G., Sir John Wolfe Barry, K.C.B., Sir Frederick Bramwell, Bart., Sir Douglas Fox, Mr. G. Ainsworth, Mr. William Dean, Mr. A. Denny, Mr. J. Allen McDonald, Mr. E. Windsor Richards, Mr. James Riley, Prof. W. C. Unwin, F.R.S., and Dr. J. H. T. Tudsbery (hon. secretary). Mr. Leslie S. Robertson, of 28, Victoria Street, S.W., has been appointed secretary to this committee, which has already commenced its work by taking evidence tendered by engineers, manufacturers and contractors bearing upon the subject of the inquiry.

THE Société des Amis des Sciences physiques et mathematiques at Poltava, Russia, is making arrangements to celebrate the centenary of the birth of Michel Ostrogradsky at Poltava on September 12-25 next.

THE following gentlemen have been elected to fill up vacancies in the list of foreign members of the London Mathematical Society:—Prof. Ulisse Dini, Pisa; Prof. Georg Cantor, Halle-a-Saale; and Prof. David Hilbert, Göttingen.

THE Berlin correspondent of the *Times* announces that an office has been opened in Berlin in order to co-operate in the preparation of an international catalogue of scientific literature. Dr. Oscar Uhlworm, chief Royal librarian, has been appointed to direct the work of the office.

THE Royal Horticultural Society will hold an exhibition of lilies at their Chiswick Garden, on Tuesday and Wednesday, July 16 and 17. On July 16 a conference on lilies will also take place in the Garden. The chair will be taken by Mr. H. J. Elwes, F.R.S., who will deliver an opening address on lilies discovered or brought into cultivation since the issue of his monograph on the subject.

THE fifth malarial expedition of the Liverpool School of Tropical Medicine, consisting of Major Ronald Ross, F.R.S., and Dr. Logan Taylor, left Liverpool for Freetown, Sierra Leone, on Saturday morning in the steamship *Axim*. It is proposed to attempt the extermination of the Anopheles mosquito on the West African Coast. The expedition has been equipped, free of expense, with large quantities of cement, petroleum, creosote and other means of attacking the Anopheles' breeding-grounds. The most dangerous time of the year, when the rainy season is at its worst, has been chosen as the most likely to test the efficacy of the intended operations.

AT a meeting of the subscribers to the Symons Memorial Fund, held on Tuesday, June 11, the executive committee reported that the proposal that the memorial to Mr. G. J. Symons, F.R.S., should take the form of a gold medal had been approved, and that the sum of 713*l.* 14*s.* 7*d.* had been subscribed for that purpose. After paying for the dies for the medal and the expenses of printing and postage, there remained a balance of 621*l.* 14*s.* 4*d.*, which the treasurer was instructed to hand over to the Royal Meteorological Society for the interest on the same to be used for the awards of the medal. It was resolved that the medal should be awarded biennially for distinguished work done in connection with meteorological science, irrespective of sex or nationality.

AT the summer meeting of the Institution of Naval Architects, to be held at Glasgow on June 25-27, Lord Glasgow, president of the Institution, will occupy the chair. Among the papers to be read are:—"On the Limit of Economical Speed of Ships," by Mr. E. T. D'Eyncourt; "On Screw Propellers" (abstracts of two papers by M. Drzewiecki); and "The Adoption of a Rational System of Units in Questions of Naval Construction," by M. Hauser, chief engineer in the French Navy (retired). The dinner of the Institution will be held on June 26 in the grounds of the Glasgow Exhibition, and will only be open to members and the official guests. The festivities include a conversazione at the invitation of the Lord Provost and the Corporation, a garden party at Kelburne, Lord Glasgow's seat, a reception at the University at the invitation of Principal Story and the Senate, and a cruise on the Firth of Clyde.

WE are indebted to *Science* for the following items of news:—Prof. Ira Remsen, professor of chemistry in the Johns Hopkins University since its foundation in 1876, has been elected president of the University.—A committee consisting of Prof. Ira Remsen, J. S. Ames and W. H. Welch has been appointed to arrange a memorial to the late Prof. Henry A. Rowland.—It is announced that Mr. John D. Rockefeller has given 200,000 dollars for the foundation of an institute for medical research, and it is understood that this fund will be increased as needed. At present America lacks an institution corresponding to the Pasteur Institute in Paris or the Jenner Institute in London. It appears that this need will be met by Mr. Rockefeller's gift, though the exact scope of the institution is still under consideration.

THE Council of the Society of Arts attended on Friday last at Marlborough House to present the King with the Albert medal of the society, which, as already announced, had been awarded to His Majesty "in recognition of the aid rendered by His Majesty to arts, manufactures and commerce during thirty-eight years' presidency of the Society of Arts, by undertaking the direction of important exhibitions in this country and the executive control of British representation at international exhibitions abroad, and also by many other services to the cause of British industry." The King said that he accepted the interesting medal, founded in memory of his lamented father, with much pleasure, because, during his long association with the Society of Arts as its president he had always taken a warm interest in its proceedings and its success. A special reason which enhanced the gratification with which he accepted the medal was that not many years ago he had himself, as president of the Society, presented it to his beloved mother, her late Majesty Queen Victoria. His Majesty added that, although he had retired from the active duties of the presidentship, he would continue to take a warm interest in the Society as its patron.

PROF. RAY LANKESTER has now received the case shipped at Mombasa on April 19, containing the skin and two skulls of the remarkable new giraffe-like animal obtained from the Semliki forest by Sir Harry Johnston, and sent by him for preservation in the Natural History Department of the British Museum. Writing to the *Times* with reference to the specimens, Prof. Lankester says: "The animal is a giraffe-like creature devoid of horns, with relatively short neck and with colour stripes on the limbs, but nowhere showing spots or areolæ like those of the giraffe. Sir Harry Johnston was amply justified in assimilating the animal to the extinct Helladotherium, but after an examination of the skulls I am of opinion that the 'Okapi' (the native name by which the new animal is known) cannot be referred to the genus of the Helladotherium, but must be placed in a new genus. I must say that, although the horny hoofs are not present, yet the double bony supports of the hoofs are preserved with the skin, and leave no doubt, even without reference to the accompanying skulls, that the animal which bore the skin was not a horse-like creature, but one with cloven hoofs."

IT is proposed to hold an exhibition on an extensive scale at Bendigo at the end of this year, under the auspices of the Government of Victoria, to commemorate the discovery of gold in 1851, and to celebrate the jubilee in a manner that will rank as a fitting memorial of the first anniversary of the Australian Commonwealth. Prominence will be given to the gold-mining and other mineral resources, and phases of mining in Victoria and other States, and special courts will be erected for the display of manufactures and industries, wool, agriculture, dairying machinery, &c. The Bendigo School of Mines will provide a model laboratory for the Exhibition, equipped with furnaces and apparatus for metallurgical and chemical work. There will be five main divisions of the exhibits and twenty-five sections, in which the applications of science to mining and to the development of other natural resources will be well represented.

DURING the past week the use of wireless telegraphy upon ocean liners has been satisfactorily demonstrated. A series of messages were despatched and received by passengers on the Cunard liner *Lucania*, which sailed from Liverpool on Saturday, and also by passengers on the Elder Dempster liner *Lake Champlain*, which reached the Mersey from Montreal on Monday afternoon. Stations have been established by the Marconi Company in connection with the Post Office wires, so that telegraphic messages can be received or despatched by passengers *en voyage*, the communication between the station and the vessel being by wireless telegraphy. The number of these stations is, as yet, not large, but there are enough of them to enable communication to be maintained, though with considerable intervals, from the time the vessel leaves Liverpool till she is an hour or so past the Fastnet. While in the Mersey she can speak with the training-ship *Conway*. As she steams along the north coast of Wales she gradually becomes within range of the station at Holyhead, which is about sixty-four miles from Liverpool. The next station is at Rosslare, in the south-east corner of Ireland, about ninety miles from Holyhead, and the last station is Crookhaven. Homeward bound vessels can pick up the stations in the reverse order. On Monday communication was established with Crookhaven by the *Lake Champlain*, and numerous service and private telegrams were despatched notifying the steamer's safe arrival off Ireland. The next station communicated with was Rosslare when forty-five miles distant. For more than five hours there was a continuous stream of messages, upwards of fifty being sent. Communication was next established with Holyhead, greetings being interchanged at a distance of 33½ miles. When 37¾ miles from Liverpool a message was received from the owners and orders were despatched instructing the captain to disembark passengers at the Princes' landing stage.

A SERIES of fine radiographs obtained by Dr. G. H. Rodman, of East Sheen, has been sent to us by Messrs. Cox and Co.; and as we admire the minute details shown by them, we appreciate the remarkable advances made in Röntgen ray photography since the first pictures were obtained six years ago.

1 Ampullaria. 2 Murex. 3 Eburna.
4 Cassis. 5 Struthiolaria. 6 Dolium (young).
7 Turritella. 8 Bulla. 9 Voluta.

Four years ago a series of radiographs of all the British batrachians and reptiles was prepared by Messrs. Green and Gardiner and published. The application of Röntgen rays to biological study was well exemplified by these pictures, and also by radiographs of molluscs obtained later by the same observers, one of an entire Nautilus and another of an entire Chiton being particularly memorable. The uses of radiography to the study of the shells of the Mollusca are, however, not so well known as they deserve to be, and we are glad to direct attention to the accompanying pictures obtained by Dr. Rodman. The correct systematic position of many forms depends on the presence or absence of certain plaits, or folds, or tooth-like projections, either on the central shelly pillar (columella) or on the inner sides of the outer wall of the shell. These are frequently so situated as to be invisible through the aperture, and when only a single specimen may be available, which it is undesirable to sacrifice in the cause of science, the utility of radiography in this connection at once becomes apparent. The evidence of the accidental inclusion of a smaller shell (it is too large for an embryo) in No. 7 is noteworthy. Radiography may also be able to determine the mineral condition of the shell, whether the carbonate of lime in its substance takes the form of calcite or arragonite, or of the one in the young and the other in the older shell, as would almost seem to be the case in No. 7. On this point, however, further research is necessary. In the case of the recent Nautilus shell, the Röntgen process shows the details of every septum and the siphuncle with great clearness, as may be seen by reference to plate xv. of vol. xi. of the *Proceedings* of the Malacological Society of London. For the benefit of those who may wish to emulate Dr. Rodman, we may add that the exposure employed by him was 80 seconds at a distance of 11 inches on an Imperial Special Rapid plate, using a Cox 10-inch spark coil and their "Record" focus tube. This is the tube which has just been awarded the gold medal given by the president of the Röntgen Society, Dr. John Macintyre.

WE have received from the president of the International Aëronautical Committee a preliminary account of the balloon ascents on May 14. Eighteen ascents took place, including manned and unmanned balloons, of which six were at Berlin, four at Strassburg and three at Vienna. Two of the unmanned balloons have not yet been found. The highest altitudes were reached by the French balloons. One of these ascents, made from Chalais-Meudon, was particularly interesting: at starting the temperature was 15°·8 C., zero was recorded at 3661 m., −50° at 9640 m., and the lowest temperature, −55°·8, at 11,025 m.; but an inversion of temperature afterwards occurred, and on reaching the greatest altitude, 15,414 m., the thermometer had risen to −32°·2. Two balloons were sent up from Trappes (near Paris): one at 2h. 30m. a.m., which recorded 0° at 2740 m. and −64° at 11,400 m.; the other, at 8h. a.m., recorded zero at 2900 m. and −60° at 11,200 m. On this occasion no balloon was sent up by this country.

THE new standard pentane ten-candle-power lamp and the new form of photometer, prescribed for use in the official gas testing-stations in London, were described by Prof. Frank Clowes at a meeting of the Incorporated Gas Institute on Wednesday, June 12. The source of light in the new lamp is the flame produced by burning, under suitable and definitely prescribed conditions, a stream of carburetted air. The carburetting liquid is the light petroleum known under the chemical name of pentane. The liquid pentane evaporates rapidly at ordinary atmospheric temperatures, and the vapour which it produces is rather more than two and a half times as heavy as atmospheric air. As the name of the lamp implies, its flame has been shown to give under prescribed conditions a constant illumination equal to that furnished by ten standard candles. The new photometer differs in its arrangement from the bar-photometers which were previously in use in the fact that the flames under comparison are upon one side of the translucent screen, whereas in the old forms the burners were placed on opposite sides of the illuminated screen. But another essential difference from the older forms of photometer, which provided for one fixed and one travelling source of light, is that in the new photometer both sources of light are fixed in position at accurately measured distances from the observing screen. The equating of the illumination of the screen is brought about by adjusting the supply of the gas which is being tested to the Sugg's London argand-burner. The new photometer and standard lamp have now been in use for some time in the fixed testing-stations and in different buildings in the area of the county of London. The gas-examiners who have constantly employed the new apparatus express a decided preference for it as compared with the bar-photometer; and they have readily adapted themselves to the somewhat special manipulation and observation which it requires

THE phenomenon of "accidental double refraction," which occurs in liquids when these are subject to changes of shape, or, to describe more correctly, rates of strain, forms the subject of an article by Prof. Ladislaus Natanson in the *Bulletin* of the Cracow Academy. The author gives an investigation, mainly hydrodynamical, of the case where the rates of strain are produced in a viscous liquid contained in the space between a rotating cylinder and a concentric cylindrical envelope. A formula is found connecting the angular velocity of the cylinder with the double refraction per unit length, and this formula appears to agree well with some of the experimental results of Umlauf and De Metz.

AN illustrated article on the Kress flying machine appears in *Die Umschau* for June 8. As has been stated in previous accounts in several journals, the apparatus is a multiple winged machine attached to a light boat, and the proposed method of experimenting is to drive the boat through the water until a sufficient speed has been attained for the thrust on the wings to cause it to rise from the surface. The writer of the article, however, evidently considers that the construction of the "air ship" has been somewhat prematurely pushed forward, seeing that the most important part of the apparatus, namely, the motor, is not yet ready. He also is of opinion that the problem of landing has not been sufficiently studied. Several experiments have already been made with the apparatus, without, however, leaving the water; but it will be when the machine has been made capable of lifting itself into mid-air that the chief difficulties of the investigation will arise.

THE fourth annual dinner of old students of the Central Technical College will be held on Wednesday, July 3, with Prof. O. Henrici, F.R.S., in the chair. Tickets can be obtained from the honorary secretary, Mr. Maurice Solomon, 12 Edith Road, West Kensington.

CAPTAIN STANLEY FLOWER sends us his Report, as director, of the Ghizeh Zoological Gardens for the year 1900. The list of donations is a satisfactory one, and we are glad to note that very much has been effected during the year in the way of adding new buildings and improving old ones, as well as in making additional aviaries and enclosures in the gardens.

IN the first part of a new biological journal—the *Bulletin* of the Brooklyn Institute—Mr. A. G. Mayer discusses the variations displayed by a species of Medusa from the Florida seas. The species in question is considered to have been derived very recently from a form common in Florida waters, but to be so distinct as to constitute a genus by itself. "It is remarkably variable, and its great commonness attests to its successfulness in the struggle for existence. In its variations it illustrates the manner in which other newly arisen races of animals may have suddenly given rise to still more diverse species."

PARTS ii. and iii. of the third volume of *Annotationes Zoologicae Japonenses* are devoted to a list of the fishes of Japan, by Messrs. Jordan and Snyder. A total of 686 species are recognised. Apart from its importance to the students of ichthyology, this communication is worthy of the best attention of those interested in the distribution of marine animals, as the authors have been enabled to divide the Japanese marine fish-fauna into four distinct groups. There are the northern or Yezo group, the temperate or Nippon group, the semitropical or Kiusiu group, and the Bassalian or deep sea group. The fish fauna of the Kurile Islands, which is probably very similar to that of Kamchatka, belongs to a distinct subarctic group, while that of Formosa probably pertains to the tropical Malayan assemblage.

THE structure of the hairs of the Patagonian ground-sloth and of the living South American edentates forms the subject of an essay by Dr. W. G. Ridewood, which appears in the May issue of the *Quarterly Journal of Microscopical Science*. The most generally interesting of the author's observations are those relating to the hairs of the two living types of sloth, and the structure which permits of the growth of an alga in each. In the three-toed sloth the hair is invested with a thick extra-cortical layer. "The layer has a tendency to crack in a transverse direction, and in the cracks there come to lodge unicellular algæ, to which Kühn has given the name *Pleurococcus bradypi*. The moisture of the climate in which Bradypus lives enables the alga to live and propagate in this curious position, and the sloth acquires a general green tint which must render it very difficult to distinguish as it hangs among the green foliage." In the two-toed sloth, on the other hand, the bulk of the hair is composed of cortex which is longitudinally fluted or grooved, the grooves being filled with strands of extra-cortex in which flourishes an alga (*Pleurococcus choloepi*) distinct from the one infesting the hairs of the three-toed species. Of quite a different type are the hairs of the ground-sloth, which are smooth and solid, Dr. Ridewood rejecting the idea of Dr. Lönnberg that they were originally coated with a cortex that has now perished. An important biological contribution to the same journal is the life-history of a North American bivalve mollusc, *Nucula delphinodonta*, by Prof. G. A. Drew, of the University of Maine.

UNDER the title of "Zoological Gleanings from the Royal Indian Marine Survey Ship *Investigator*," Major Alcock has collected together the biological observations made by the different medical officers who have served on board during his own connection with the vessel. These observations, the author tells us, are buried in reports that are not readily accessible, or scattered through papers on systematic zoology where they may easily be overlooked. The observations are arranged under eight headings, namely, commensalism; sexual characters, pairing and viviparity; sounds made by marine animals; notes on stalk-eyed crustaceans; instances of protective and warning coloration; phosphorescence; peculiarities in food of marine animals; and notes on reptiles and fishes. The "gleanings" are really a mine of information to the naturalist, and the author has rendered a distinct service to his fellow-workers in producing them in their present form. Among notable instances of commensalism is the case of the hermit-crab protected by a bag of sea-anemones. Another instance has often been observed on the reefs of the Andamans, where a crab of the genus Cryptodromia is protected by a sponge, which is shaped like a cap and tightly fitted to the crustacean.

GEOLOGICAL students and others interested in the science of the earth will find many desirable works in a classified catalogue of books and pamphlets on geology just issued by Messrs. Wesley and Son. The catalogue contains no less than 2225 titles of works in various departments of geological science, classified under 28 headings. It includes the geological library of the late Mr. G. H. Morton, of Liverpool. A glance through the catalogue will repay any geologist anxious to increase his library.

The cryptogams collected by Dr. F. Welwitsch in 1853–1861 are described by the botanists who have determined them in the new volume (vol. ii. part ii.) of the "Catalogue of Welwitsch's African Plants," published by the trustees of the British Museum. Though the plants were collected more than forty years ago, the collection is in some respects the most extensive and representative yet obtained from Africa. The species now described belong to the vascular cryptogams, mosses, hepatics, marine algæ, freshwater algæ, diatomaceæ, lichenes, fungi and mycetozoa.

A MEMORIAL of the late Dr. George Brown Goode, together with a selection of his papers on museums and on the history of science in America, has been published in the form of a volume by the Smithsonian Institution. Dr. Goode was held in the highest regard in all places where natural science is cultivated, and this account of his life and services will be cherished by everyone who is aware of the influence he exerted upon museum development. The addresses delivered at the memorial meeting held at the U.S. National Museum are printed, and also an appreciative notice of his life and services to science, by Prof. S. P. Langley. Eight papers are published in the volume, most of them dealing with museum administration and the pursuit of natural knowledge in America. There is much of interest in these papers concerning the growth of scientific institutions in the United States, and united they form an appropriate memorial of an accomplished man.

AN interesting synthesis of some aromatic aldoximes by means of fulminating silver is described by Messrs. R. Scholl and E. Bertsch in the current number of the *Berichte*. If a polyhydroxylic derivative of benzene is dissolved in ether, some fulminating silver suspended in the solution, and hydrochloric acid led slowly into the well-cooled solution, the silver fulminate disappears and the hydrochloride of the new aldoxime crystallises out. The method has been successfully applied to resorcinol, orcinol, pyrogallol and phloroglucinol.

THE same number of the *Berichte* contains an account by C. Harries of the preparation and properties of the dialdehyde of succinic acid. The aldoxime of this aldehyde can be prepared by the method of Ciamician and Dennstedt from pyrrol and hydroxylamine, and this, suspended in water and treated with nitrous acid, gives an aqueous solution of the new dialdehyde from which the pure substance can be isolated with some difficulty by fractional distillation. Succinic aldehyde is the first member of the aliphatic dialdehydes to be isolated in a pure monomolecular form, and is of interest as being the starting-point for the preparation of the three heterocyclic rings, furane, thiophene and pyrrol. The ready convertibility of this aldehyde into derivatives of these three rings is shown experimentally in the present note.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mr. W. B. Bingham; an Otter (*Lutra vulgaris*, ♂), British, presented by Mr. W. Radcliffe Saunders; twelve Black Vultures (*Cathartes atratus*) from America, presented by Dr. E. A. Goeldi; two Cambayan Turtle Doves (*Turtur cambayensis*), a White-collared Ouzel (*Merula albicincta*), a Large Andaman Parrakeet (*Palaeornis magnirostris*), a Tickell's Flower-pecker (*Dicaeum erythrorhynchus*), a Cinnamon Tree Sparrow (*Passer cinnamoneus*), a Rufous-breasted Accentor (*Tharrhaleus strophiotus*), a Black-throated Accentor (*Tharrhaleus atrigularis*), an Eastern Meadow Bunting (*Emberiza stracheyi*), four White-capped Buntings (*Emberiza stewarti*), two Indian Button Quails (*Turnix tanki*) from British India, presented by Mr. E. W. Harper; a Northern Mocking-bird (*Mimus polyglottus*) from North America, presented by Mr. H. C. C. Gülich; an Antillean Boa (*Boa diviniloque*) from the West Indies, presented by Mr. D. F. Mackenzie; a Sykes's Monkey (*Cercopithecus albigularis*) from East Africa, a Chacma Baboon (*Cynocephalus porcarius*) from South Africa, a Smooth-headed Capuchin (*Cebus monachus*) from South-east Brazil, two Wanderoo Monkeys (*Macacus silenus*, ♂ ♀), a Banded Parrakeet (*Palaeornis fasciata*), a Ring-necked Parrakeet (*Palaeornis torquata*), two —— Snakes (*Cerberus rhynchops*), thirteen —— Fish (*Saccobranchus fossilis*) from India, a Golden-naped Amazon (*Chrysotis auripalliata*) from Central America, a Leadbeater's Cockatoo (*Cacatua leadbeateri*) from Australia, a Shining Parrakeet (*Pyrrhulopsis splendens*) from the Fiji Islands, a Blue-winged Green Bulbul (*Chloropsis hardwicki*) from British India, two Japanese Terrapins (*Clemmys japonica*) from Japan, a Blue Lizard (*Gerrhonotus caeruleus*) from Western North America, deposited; two Chinchillas (*Chinchilla lanigera*) from Chili, purchased; a Llama (*Lama peruana*), a Hybrid Lemur (between *Lemur xanthomystax* and *L. brunneus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBSERVATIONS OF NOVA PERSEI.—In the *Mem. de la Soc. degli Spett. Ital.* (vol. xxx. pp. 77–90), Prof. A. Ricco describes the observations of the brightness and spectrum of Nova Persei, made at the Catania observatory. The various magnitudes given are similar to those already published by other observers, the light curve showing distinct oscillations from March 8.

The spectra were observed with the Merz refractor of 0·33 metre aperture and McClean star spectroscope, and photographs obtained with the photographic equatorial and Vogel spectrograph, the spectra being about 43 millimetres long, with exposures of one hour. The wave-lengths are given as follows:

3933 K	... 4179	... 4541	... 4923
3969 H	... 4235	... 4587	... 5019
4015	... 4310	... 4609	... 5168
4039	... 4341 Hγ	... 4636	... 5300
4071	... 4412	... 4681	... 5551
4102 Hδ	... 4493	... 4862 Hβ	... 5627

COMET 1901 *a*.—The comet is now getting so far away from the sun that it is in all probability beyond the reach of any but the largest instruments. The following ephemeris may be of service to those having sufficient optical power:—

Ephemeris for 12h. Berlin Mean Time.

1901.	R.A. h. m. s.		Decl. ° ′
June 21	7 24 56	...	+10 8·3
23	28 6	...	10 16·1
25	31 9	...	10 23·1
27	34 7	...	10 29·5
29	7 37 0	...	+10 35·2

NEW VARIABLE STARS:—

74, 1901 (Persei). Herr P. Guthnick, of Bonn, finds that the star

$$\left.\begin{array}{l}\text{R.A.} = \ \ 3^{h}\ 2^{m}{\cdot}7\\ \text{Decl.} = +44^{\circ}\ 29'\end{array}\right\}(1900)$$

is variable to the extent of 0·6 magnitude. From the table of magnitudes given the period would appear to be about thirty days, but the gaps are too long for any accurate estimate. This star is the intensely orange-coloured χ Persei.

75, 1901 (Persei). Herr Fr. Deichmuller, of Bonn, finds variability in the star 36 Flamsteed, amounting to about 0·5 magnitude. The observations indicate a change from 4·92 to 5·65 magnitude twice a month. The variability of this star is confirmed by Herr Guthnick (*Astronomische Nachrichten*, Bd. 155, No. 3720).

FORMS OF IMAGES IN STELLAR PHOTOGRAPHY.—In the *Annals* of Harvard College Observatory (vol. xli. No. vi. pp. 153–187), Mr. E. S. King, the observer in charge of the photographic department at that institution, describes the various disturbing causes which affect the forms of star images obtained by photographic methods with different systems of following. The chief of these are irregularities of the driving clock, differential refraction, and flexure. To correct these errors two methods of guiding have been employed, the plate being moved by suitable adjusting screws, either with the telescope or independently of it, the latter method being preferred, as it permits, not only corrections in two coordinates perpendicular to each other, but also a rotary movement for the elimination of flexure and differential refraction.

The investigations described have been in hand since 1896, when they were undertaken in consequence of difficulties occurring in the observation of the Algol variable W Delphini at low altitudes. A fourth source of error, in the adjustment of the polar axis, must be also considered, and it is practically important to do this, inasmuch that by an accurate knowledge of the conditions it is possible to introduce such an amount of error from this and the clock rate as to partially eliminate the variable errors due to flexure, &c. After insisting on the necessity of the clock having as continuous and regular motion as possible, it is pointed out that the correct rate for following is not sidereal time, as is commonly supposed, but a variation from this depending on the latitude and the declination of the object. The equations of condition are developed for determining the proper following rates for various localities. The actual path of a star on the plate as affected by refraction may be either a parabola, hyperbola, ellipse or circle. The effect of error of the polar axis is an elliptical form of star image, varying with the declination. The analytical investigation of this shows that the refraction in declination can to a great extent be eliminated by an alteration of the inclination of the axis; this is now provided for in many instruments by the frequent shifting of the polar axis by known amounts. The correction for the right ascension component is more complicated, and tables are given showing the changes per hour for various hour angles. Reproductions from photographs taken with clock rate adjusted for refraction and polar axis elevated are shown. In considering the effects of flexure three kinds are discussed, affecting either the polar or declination axes, and the tube. Various methods actually in use at the Observatory for determining the flexure are then described in detail, also the exact method of varying the load of the control pendulum governing the driving clock. The effects of temperature on the trails have also been considered, and methods for its elimination.

As the result of the investigation, it is found that plates of 60 minutes' exposure may be taken without visual following, which shall have images not exceeding 0·01 cm. in elongation due to the clock, and a photograph of the cluster in Hercules taken in this way is reproduced. Several special applications of these principles are then discussed, including the important one of photographing stellar spectra with the objective prism, where the spectrum lines are often very oblique, thus lessening the dispersion and possibly the definition. A table is calculated showing that this may be corrected by a slight rotation of the prism for each star.

Several methods for the mechanical correction of flexure are indicated, and finally the special means for correcting proper motions of the object under examination are considered, examples of the photographs of Eros being given in illustration.

THE SIXTH ANNUAL CONGRESS OF THE SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES.

THIS Congress was held at Haslemere and Hindhead on June 6-8, and delegates and members representative of most of the affiliated societies upon the Union's list were in attendance. There were, further, a goodly number of visitors present, attracted to a large extent by the unbounded hospitality of the residents and admirable arrangements of the local committee, which were most elaborate and highly successful.

The proceedings were opened by Prof. G. B. Howes, F.R.S., who, as the retiring president, in a few apposite remarks resigned the chair to his successor, Mr. G. A. Boulenger, F.R.S., who then delivered the annual address. Taking for his subject the field-work and results of experiment of the past quarter of a century upon the European Reptilia and Batrachia, he led up to the formulation of a revised list of the British species. He then dealt in greater detail with those genera and species inhabiting the immediate neighbourhood of the meeting, special interest attaching to some facts involving the natterjack and Gilbert White's area of observation, in their relation to the topic of batrachian migration; and he seized the opportunity to enlist the services of local naturalists in the study of this problem, in the better working-out of the varieties of the common viper, and in other allied herpetological matters for which the study of the local fauna presents a favourable opportunity. Beyond this the address, which was admirably suited to the occasion, contained historical records of permanent value and some wholesome advice to the collector and would-be specialist, based upon the author's great experience of herpetological affairs.

The meetings for strictly scientific business were confined to the Friday and Saturday mornings, five papers being read. An unusual departure, however, was entered upon, in the substitution of three short addresses for the musical entertainment customary on similar occasions at the evening *soirée*. The reception at this was by Sir F. Pollock, Bart., and in his capacity as president of the local natural history society he delighted those present with a felicitous speech. The short addresses which followed this were by Mr. G. F. Chambers, on "An Eclipse Trip to Portugal in 1900"; by Mr. Oswald Latter, of the Charterhouse, on "Cuckoos' Eggs"; and by Dr. Jonathan Hutchinson, F.R.S., on "Habit and Discipline in their Influence on Organisation." The latter, on the lines of the famous Sunday afternoon discourses with which the indefatigable doctor is in the habit of improving the minds of his friends and visitors, both at Haslemere and in London, was noteworthy for the attempt to prove that the orbital bulla of the hippopotamus, shown to be different in origin in each of its two stages of development, is, like that of the gavial, functional as a support for the eye during protraction and elevation; and for the thesis that in human affairs the poet must precede the philosopher.

Dr. Hutchinson further contributed to the educational success of the meeting by entertaining the assembled guests at his private museum at College Hill, the originality of the plan of arrangement of which was much admired; and, with characteristic versatility, he followed this up by leading the way to Lord Tennyson's abode at Blackdown, before which, after a visit to its interior, verses appropriate to the occasion were by him and others recited.

Of the papers read at the ordinary meetings, the first, by the Hon. Rollo Russell, on "Moisture in the Atmosphere," is the embodiment of a lengthy series of experimental and statistical observations which will be of much service for reference. This was followed by a paper by Miss E. Sargent on "Seedlings," chiefly noteworthy for some observations made in conjunction with "a colleague," in which a downward displacement of the seed by forcible contraction of the roots was fully described and illustrated by an ingenious model. Prof. Howes concluded the first morning's work with a short lecture, which he said was pertinent to his presidential address of the previous year. He dealt with the principle of "convergence," as applying more especially to recent work among the Mammalia and Batrachia ecaudata, and with "substitution" in its bearings on the study of the electrical organs of fishes.

The afternoon of Friday was given to the reading of a couple of papers on "The Teaching of Nature Knowledge in Elementary Schools," by Miss M. A. Buckton, who has had considerable experience of elementary school-work both on the Continent and at home, and by Prof. A. D. Hall, principal of the Wye Agricultural College. Upon these a discussion arose, which, for lack of organisation beforehand and time for extension, fell short of what might have been an important issue.

The concluding paper of the meeting was by Mr. S. T. Dunn, secretary to the Director of Kew Gardens, under title "The Origin of Certain Weeds." The author read an account of the geographical distribution of certain dead nettles, and in the short discussion which ensued doubt was expressed whether he had pointed to anything which does not apply to certain other British plants well known, while there arose a difference of opinion which left the audience in uncertainty as to what constitutes a "weed."

At the meeting of delegates, which closed the proceedings, the question of subscription was discussed; and conspicuous among the motions passed was one of appeal to the Brighton Town Council, who are about to take the famous Aquarium of that town in hand for development, to make adequate provision for scientific investigation and work in economics, in a manner which was agreed upon.

The exquisite country in which the meeting was held and the delightful weather which prevailed proved both beneficial and attractive, and not the least pleasurable feature of the Congress was the manner in which the influential residents, both by their generous hospitality and personal interest, contributed to its success, while the vociferous croaking of some introduced frogs came as a most appropriate accompaniment to the proceedings.

The Congress for 1902 is to be held at Canterbury, under the presidency of Dr. Jonathan Hutchinson, F.R.S., who has served the recent one so well.

SOME RECENT WORK ON DIFFUSION.[1]

II.

WE have seen that when steady diffusion is going on down a cylindrical column which is absorbent at the bottom there is a uniform diminution in the density of the diffusing substance from one end of the column to the other, evidenced in the case of a coloured substance by a gradual and uniform thinning out of the colour in the direction of the axis of the column. But in any horizontal cross-section of the column the colour is of the same intensity in all parts of the section, which means, of course, that the diffusing substance is of equal density along these planes.

In a diagrammatic section of such a column we should therefore represent the surfaces of equal density by straight lines drawn at right angles to the axis of the cylinder, and the stream lines of the diffusing substance by straight lines drawn parallel to the axis.

I am able to show you the horizontal lines of equal density in a cylinder, produced by a process of intermittent diffusion presently to be described.

When diffusion goes on into a flat absorbent disc, or aperture, instead of into a cylinder, it is clear that the stream lines of the diffusing substance must strongly converge towards the disc instead of moving vertically downwards as they do in the cylinder, and it is also clear that the lines or surfaces of equal density in the diffusing substance must form curved surfaces of some kind over the disc. We must now consider the exact form which these lines and surfaces will take.

It so happens that there is a problem in electrostatics which is analogous to the one before us, and it is one which has been fully worked out by mathematical physicists.

When an insulated conductor receives an electric charge the form taken by the surfaces of equi-potential around the conductor

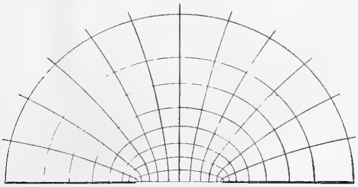

FIG 1.

depends on its shape, and on the nature and distribution of other charges in its neighbourhood.

If we suppose the absorbing disc or perforation used in our diffusion experiments to be replaced by an electrified disc of similar dimensions, embedded flush in a wide non-conducting rim, then the surfaces of equal electric potential in the air above the disc will take the form represented in Fig. 1. The surfaces will form a series of hemi-spheroids which in any vertical section passing through the centre of the disc will give a series of ellipses, having their common foci in the edges of the disc. Faraday's lines or tubes of force, on the other hand, will in this case be represented by a series of hyperbolas, also having their foci in the edges of the disc.

Now we have every reason to believe that in a diffusion experiment with an absorbent disc the surfaces of equal density of the diffusing substance over that disc are the exact analogues of the surfaces of equi-potential over the similar electrified disc, and that the stream lines of the diffusing substance are the analogues of the lines or tubes of force. If this is so the diagram will equally well represent an experiment in which, for instance, the carbonic acid of perfectly still air is being absorbed by a disc of soda solution, surrounded by a wide rim.

Fig. 2 represents what we might expect to be the state of things when diffusion takes place through a circular aperture in a diaphragm. Here the stream lines of the substance, which are convergent as they approach the aperture, diverge again when the opening is past, and we should expect to get a double system of the ellipsoidal zones of equal density on either side of the aperture.

Did time permit I could show you that this hypothesis is not only capable of giving reasonable and consistent explanations of all the phenomena of diffusion into and through apertures, but completely explains the "diameter law," and also enables us to predict the amount of gas, vapour, or solute which will pass under given conditions, and the results can be verified by experiment.

I have only time to glance at one or two readily verifiable deductions from this hypothesis. In the first place, it fully accounts for what I have called the "diameter law," that is to say, that diffusion through circular apertures in a diaphragm is proportional to their diameters, not to their areas.

In two diagrams on the wall we have represented the arrangement of the equi-density curves and stream lines over two absorbent discs, one double the diameter of the other. We may take these discs to represent an alkaline solution absorbing carbonic acid from the air.

The two systems are on the same relative scale, but one is magnified by two diameters.

It will be seen that a curved line corresponding to any given actual density of the diffusing substance must be twice as far from the surface of the larger disc as it is from the surface of the smaller; that is to say, the *gradient of density* on which the flow depends is twice as steep over the small disc as it is over the large one. From this it follows that for equal areas the flow into the smaller disc is twice that into the larger and that the *total* flow must be proportional to the diameters, which is just what is found to be the case

Wherever we get conditions favourable for the formation of a

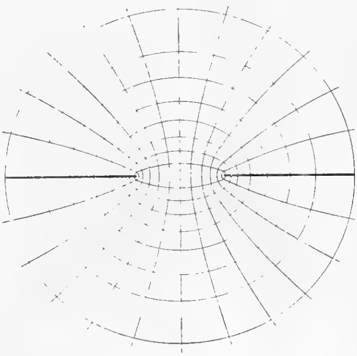

FIG. 2.

system of equi-density zones on one or both sides of a perforated diaphragm, diffusion will go on in accordance with this "diameter law." But one system of zones is quite sufficient for the purpose, so that in a case like that of Fig. 2, which represents the course of diffusion of atmospheric CO_2 in perfectly still air into an absorbent chamber, we might allow the outer system of equi-density shells over the aperture to be completely swept away by air currents, and still the "diameter law" would hold good on account of the inner series of zones, which, from their position, are protected from the air currents. This explains in a very satisfactory manner why it is much more easy to demonstrate the diameter law with apertures in a diaphragm than simply with absorbing discs, where only one external system of equi-density shells can exist, which is, of course, extremely liable to be influenced by disturbing currents.

Satisfactory, however, as this hypothesis is in explaining everything connected with these curious facts of diffusion, it must be borne in mind that the reasoning on which it is based is in part deductive and in part dependent on an analogy.

Nearly 300 years ago it was said by Sir Thomas Roe that "many things hold well in discourse, and in the theorique, satisfie curious imaginations, but in practice and execution are found difficult and ayrie."

Fortunately this does not apply to the present case, and I am able to bring before you this evening for the first time an experimental demonstration of the existence of zones of equal density in the neighbourhood of an aperture through which diffusion is

[1] Discourse delivered at the Royal Institution, Friday, March 22, by Dr. Horace T. Brown, F.R.S. (Continued from p. 174.)

going on, and to show you that they have the exact shape which the theory requires.

I have here a rectangular glass cell divided horizontally by a thin plate of celluloid having a circular hole punched through it. The lower half of the cell is filled with a solution of gelatine containing a little barium chloride, and the upper half with a solution of sodium sulphate.

The relative strengths of the solutions are so adjusted that the two salts, diffusing in opposite directions, shall meet somewhere in the gelatine where a precipitate of barium sulphate is thrown down at the surfaces of contact of the two opposing streams of diffusion. The result is that we get a slowly growing, spheroidal mass of precipitate, starting from the aperture and resembling in shape the head of an inverted mushroom.

If we arrange for the diffusion of the sodium sulphate to be intermittent, or, better still, if we alternate the diffusion of a sulphate with that of a chromate, we get well-marked *zonings* in the precipitate forming the spheroid, zonings which correspond to the successive forms which the spheroid has assumed during growth, and which, therefore, must have been zones of equal density of the diffusing substances. We can study the forms which these assume in relation to the aperture by subsequently cutting sections through the gelatine, but by a little arrangement we can make the apparatus cut its own sections as the diffusion goes on.

This is done by making the aperture in the diaphragm *semi-*

FIG. 3.

circular instead of circular, and bringing its straight edge close up to the side of the glass vessel.

I will now throw on the screen some photographs of vertical sections of spheroids of diffusion of this kind. (See Fig. 3 and Fig. 4).

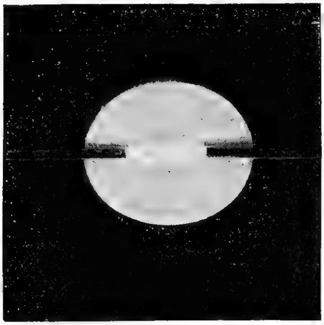

FIG. 4.

On comparing the lines of equal density around the aperture with the diagrams on the wall you will at once see that their shape is exactly that required by theory—they describe a series of ellipses having their common foci in the edges of the aperture through which the diffusion is taking place.

The actual stream lines of the diffusing substance are not visible, but as these must necessarily be normal to the curves of equal density they can only be represented by a series of hyperbolas, also having their foci in the edges of the aperture.

The electrostatic analogy which has served us so well in determining the form of the zones of equal density around *single* apertures may also be used for predicting their distribution around a series of apertures in a diaphragm.

If we regard the individual holes in a multiperforate diaphragm as so many minute discs, all electrified to a common potential, the lines of equi-potential and the lines of force should take a form something like that represented in the diagram, Fig. 5, the lines of equi-potential forming complete ellipses in the immediate neighbourhood of the electrified discs, but gradually intersecting and forming a series of wavy lines, which become more and more horizontal as the distance gets more remote.

Could they be rendered visible these are also the forms which we should expect the lines of equal density of a substance to take when it is diffusing through a series of small apertures. I am

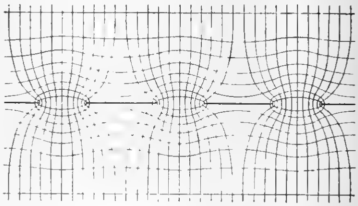

FIG. 5.

able to give you a verification of this by throwing on the screen photographs showing the result of intermittent diffusion through a series of such apertures (Figs. 6 and 7). The lines of equal density are marked out by the alternate bands of sulphate and chromate of barium as they were in the last experiment.

From the shape of these lines of equal density it is possible to determine the form of the stream lines of the diffusing substance and to show that the tendency of a multi-perforate septum of this kind is to locally increase the gradient of density in its neighbourhood and so to accelerate the flow through the small apertures. We get, in fact, a complete and satisfactory explanation of the small amount of obstruction which such a diaphragm produces when put in the way of a diffusive flow of gas or liquid.

Intermittent diffusion such as I have described may be used to illustrate in a variety of ways the distribution of electric potential around electrified bodies which are within the sphere of each other's action.

It is generally a difficult and laborious task to work out the distribution of the surfaces of equi-potential around electrified bodies which are near enough to influence each other. By this system of intermittent diffusion we may sometimes make Nature

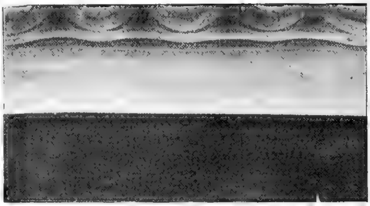

FIG. 6.

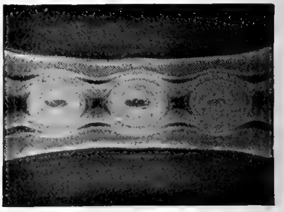

FIG. 7.

work out the problem for us. Here, for instance (see Fig. 8), is a figure copied from Clark Maxwell's "Electricity and Magnetism," representing the form which is assumed by equi-potential surfaces around two points charged with quantities of electricity of the same kind in the ratio of 4 to 1. If the analogy is correct diffusion, through apertures having their diameters in the ratio of 2 to 1 ought to give the same series of figures. You see from the photograph of an actual experiment given in Fig. 9 that this supposition is correct.

In Fig. 10 are given the calculated lines of force at the edges of two parallel plates, one of which is insulated and electrified, the other connected with the earth. These ought to correspond in shape to the equi-density lines of a substance undergoing steady diffusion from between two parallel plates, as, in fact, you see they do. (See Fig. 11).

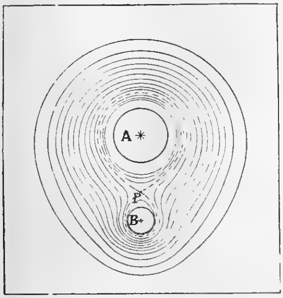

FIG. 8.

But considerations of this kind, although of interest in showing the striking analogies between certain phenomena of electrostatics and static diffusion, would carry me too far from my main subject, and I must again bring you back to the green leaf which was the starting point of my lecture.

If we regard the structure of the leaf from the new point of view which now suggests itself we can readily understand how it is that the stomates, notwithstanding the relatively small area of the leaf surface which they occupy, can drink in the atmospheric carbonic acid with such rapidity.

The finely perforated epidermis of the leaf, tightly stretched over the interior air-spaces, whose walls can absorb carbonic acid, constitutes a multiperforate septum which is under the most favourable conditions to produce an acceleration of the diffusive flow of the gas into the leaf.

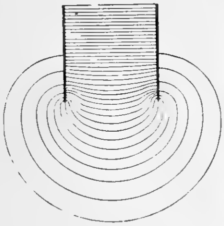

FIG. 10.

The laws of gaseous diffusion through small apertures are now so well understood that we can predict with certainty the particular quantitative effect produced on a given diffusive flow by any screen with perforations of known size and distribution providing they are not within a certain number of diameters distant from each other. These deductions can then be verified by experimenting with small shallow glass cylinders, made absorbent inside, and closed at the top with very thin discs of celluloid perforated in a known manner. Such a piece of apparatus may be regarded as an artificial leaf, the perforated celluloid representing the epidermis with its stomates, whilst the absorbing solution of caustic soda acts the part of the assimilating centres.

Having obtained confidence in the accuracy of the method of calculation we can then apply the same principles to determining the efficiency of the leaf stomates, when the whole system is regarded as a piece of mechanism for promoting diffusion.

In the first place it is found experimentally that the most economical arrangement of very small apertures is to have them set about 8 or 10 diameters apart, for at that distance the interference with each other practically ceases. *This is about the distance at which we generally find the stomates arranged on the underside of most leaves.*

You will remember that the amount of atmospheric carbonic acid which enters an assimilating leaf in an hour is about ·1 c.c. for every square centimetre of leaf. Now it can be shown that for this amount of gas to enter through the stomates it is only necessary for the CO_2 content of the air just within the leaf to be kept down to 2·8 parts per 10,000, when that of the outer air is 3 parts per 10,000. This very slight difference in the partial pressure within and without is quite sufficient to account for all the entering CO_2, thanks to the special structure of the leaf.

Thus all the apparent difficulties in the way of accepting the

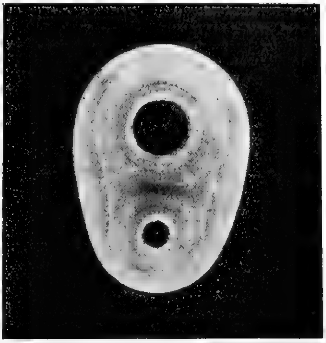

FIG. 9.

minute stomates as the sole pathways of gaseous exchange in the leaf entirely disappear when the leaf is studied in this new light, and it becomes evident that the adjustment of the mechanism of the leaf to the physical properties of its surrounding medium is far more perfect than has been hitherto suspected. The leaves of plants have, in fact, proved to be better physicists

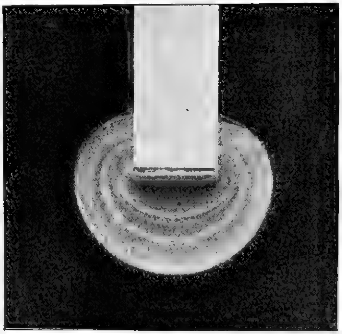

FIG. 11.

than we are, since their structure bears the impress of response to certain properties of gases of which we have hitherto been ignorant.

This is by no means the first occasion on which the plant has given us a lead in physics. The theory of dilute solutions, formulated by van 't Hoff, and indicating that the laws of Boyle and of Avogadro are as applicable to dilute solutions as they are to gases, had its origin in the observations of De Vries and of Pfeffer on the plasmolysis of living cells and the properties of natural semi-permeable membranes.

Nor can we doubt that there are many more such instances which only await detection, and we may reasonably hope that the boundaries of physics and of chemistry will be materially enlarged in unexpected directions if we pay due regard to the whispered hints and slender clues which are on all sides given by the living world of Nature.

A LONG PERIOD SUNSPOT VARIATION.[1]

IT has long been known, and Dr. Rudolf Wolf of Zurich was the first to draw attention to it, that the length of a sunspot period is only in the *mean* eleven years, and that the real length of any one period might differ from this value by as much as ± two years. Another fact of observation is that the times of maxima do not occur a constant number of years after a preceding minimum, and Dr. Wolf determined the *mean* interval as 4·5 years. The minimum also follows the maximum in a *mean* interval of 6·5 years.

It has further been noticed that the intensity of each period, *i.e.* the total amount of spotted area included between one minim um and the next, was not constant. Dr. Wolf held that

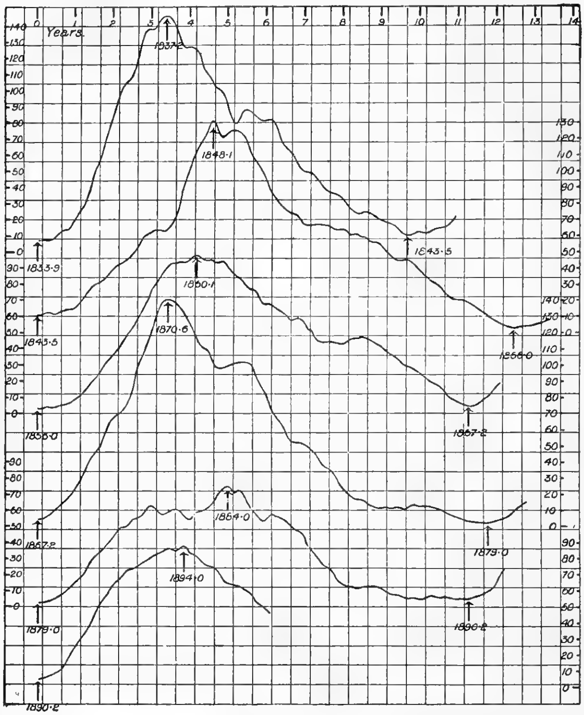

FIG. 1.

these quantities indicated a certain periodicity, and at first suggested a period of 178 years, and later 55·5 years, or a period extending over five eleven-year periods ($11·1 \times 5 = 55·5$).

The present investigation was limited to the interval of time, namely, 1833–1900, over which *systematic* observations of the sun's surface have been regularly made, and as Dr. Wolf's relative numbers agree well with the actual facts of observation over this period, these numbers have been employed.

The important magnetic results obtained by Mr. William Ellis served as a check on the whole work, since he has shown that the curves for the magnetic elements are in almost exact accord with those of the sunspots. Any variations determined from the sunspot curves should, then, have their counterpart in the magnetic curves.

Fig. 1 will give the reader an idea of each sunspot curve from minimum to minimum for the period above mentioned.

They are so arranged in order of date that each individual curve can be examined separately. The times of succeeding minima are arranged vertically under each other, so that any variation as regards acceleration or retardation of the following maxima, and any inequality in the length of the period minimum to minimum can be seen at a glance; each of these epochs is indicated in the figure by a short arrow with the corresponding dates.

Dealing with the inequalities of the interval minimum to maximum, it is found that there is a regular variation having a period of about thirty-five years. Curve B, Fig. 2, shows this variation, the abscissæ representing the time element and the ordinates the intervals minimum to maximum plotted at the epochs of the minima.

Dealing with the intervals minimum to maximum of the magnetic curves in a similar way, the result obtained is shown in the same figure, curve C.

Both these curves thus indicate that there is some law at work which introduces a secular variation by retarding periodically the sunspot maxima in relation to the preceding minima. The actual epoch of maximum relative to the preceding minimum oscillates about the mean value 4·12 years, its greatest amplitude being in the mean about 0·8 year.

Another point of great importance is that when the epoch of maximum spotted area follows in the shortest interval of time after a minimum, the spotted area for the whole period is greater than at any other time.

Thus, if the spotted area included between consecutive minima be summed up for each period, and these values, used as ordinates, be plotted at the epochs of minima, as done previously, and the curve inverted, curve D Fig. 2 is the result. It will be noticed that this curve is very similar to the two immediately above it, and shows a period of about the same length, namely, about thirty-five years. It may be here remarked that the value for the total spotted area for the period 1833·9 to 1843·5, the earliest value in point of time dealt with, is not quite in harmony with the other values. There seems, however, sufficient evidence to indicate that the small value may be due to the fact that the observations were not then made quite on a uniform plan. That the maximum of 1836 was a great one, and only equalled by that of 1870, is well known.

The discussion of these observations thus leads to the important conclusion that *underlying the ordinary sunspot period of about eleven years there is another cycle of greater length, namely, about thirty-five years.*

This cycle not only alters the time of occurrence of the maxima in relation to the preceding minima, but causes changes in the total spotted area of the sun from one eleven-year period to another.

A glance at Fig. 1 will show that the length of the period minimum to minimum seems to alternate, the magnitude of these alternations becoming smaller. An attempt was made to see if any law could be traced, but although there was a variation suspected in the length of both the magnetic and sunspot periods (reckoning from minimum to minimum), which increases and decreases in *alternate* eleven-year periods from a mean value, the observations do not extend over a sufficient interval of time to allow a more definite conclusion to be drawn.

It is generally conceded that the spots on the surface of the sun are the result of greater activity in the circulation in the solar atmosphere, and therefore indicate greater heat and, therefore, light. This being so, the curve representing the spotted area may be regarded as a light curve of the sun.

[1] Abstract of a paper, "The Solar Activity 1833–1900," read before the Royal Society on May 23, by Dr. William J. S. Lockyer.

The sun may thus be considered a variable star (1) the light of which (reckoning from minimum to minimum) is variable, with a mean value of about 11·1 years; (2) the epoch of maximum does not occur a constant number of years after the preceding minimum, but varies regularly, the cycle of variations covering about thirty-five years.

It is interesting, therefore, to know that the sun is not the only star which exhibits variations similar in kind to those mentioned above, for the light curve of η Aquilæ not only has a more rapid rise to maximum and slow fall to minimum, but the periods from minimum to minimum vary in length, and the interval minimum to maximum has a regular variation.

Since then, in addition to the well-known eleven-year period of sunspot frequency, there is another cycle which extends over about thirty-five years, and which is indicated clearly, as has been shown, both by the changes in the times of the occurrence of the epochs of maxima and in the variations in area included in consecutive eleven-year periods of both sunspot and magnetic curves, it is only natural to suppose that this long-period variation is the effect of a cycle of disturbances in the sun's atmosphere itself.

Such a cycle, if of sufficient intensity, should cause a variation from the normal circulation of the earth's atmosphere, and should be indicated in all meteorological and like phenomena.

We are indebted to Prof. Ed. Brückner for the great work on the changes in climates, and in this investigation he sought variations in the observations of the height of the waters in inland seas, lakes and rivers; in the observations of rainfall, pressure and temperature; in the movements of glaciers; in the frequency of cold winters; growth of vines, &c.

The result of the whole of the investigation led him to the conclusion that there is a *periodical variation in the climates over the whole earth, the mean length of this period being* 34·8 ± 0·7 *years*.

Prof. Brückner was so convinced of the undoubted climate variations which he deduced, and so certain that such variations could only be caused by an external influence, that he investigated Wolf's sunspot numbers to see whether such a cycle was indicated. Not finding any he was led to make the bold suggestion that such a variation as he sought must really exist in the sun, but might possibly be independent of sunspots. He finally concluded that the climate variations are the first symptom of a long period variation in the sun, which probably will be discovered later.

In the light of the secular period of solar activity dealt with in this article, Prof. Brückner's conclusions are of great interest, because not only does the length of the period, but the critical epochs of his cycle completely harmonise with those found in the present discussion of the sunspot and magnetic curves.

To illustrate more fully this connection and to take only one case, namely, rainfall, three rainfall curves which have been copied from his book are reproduced in Fig. 2 (curves E, F, G).

E and F represent the secular variations for what Prof. Brückner calls "Reguläre Gebiete I and II," while curve E is the mean for the whole set of observations he has employed, and represents the secular variation of rainfall over the whole earth so far as can be determined.

The comparison of these curves with those representing the sunspot and magnetic results given above them shows that when the epoch of maximum spotted area (curve B) follows late after the preceding epoch of minimum (1843, 1878), or when the spotted area from minimum to minimum is least (curve D), the long period rainfall curve is at its maximum or we have a wet cycle. When, on the other hand, the maximum (curve B) follows soon after the preceding minimum (1867), and the spotted area for this cycle is at a maximum (curve D), the rainfall curve is at a minimum or a dry cycle is in progress.

Prof. Ed. Richter, in a detailed investigation of the movement of glaciers, has also found a cycle of thirty-five years, and he pointed out that the variations agreed generally with Brückner's climate variations, the glacier movement being accelerated during the wet and cool periods.

Again, Mr. Charles Egeson not only finds a secular period of about thirty-three to thirty-four years in the occurrence of rainfall, thunderstorms and westerly winds in the month of April for Sydney, but the epochs of maxima of the two latter harmonise with the epochs of the thirty-five yearly period deduced for sunspots.

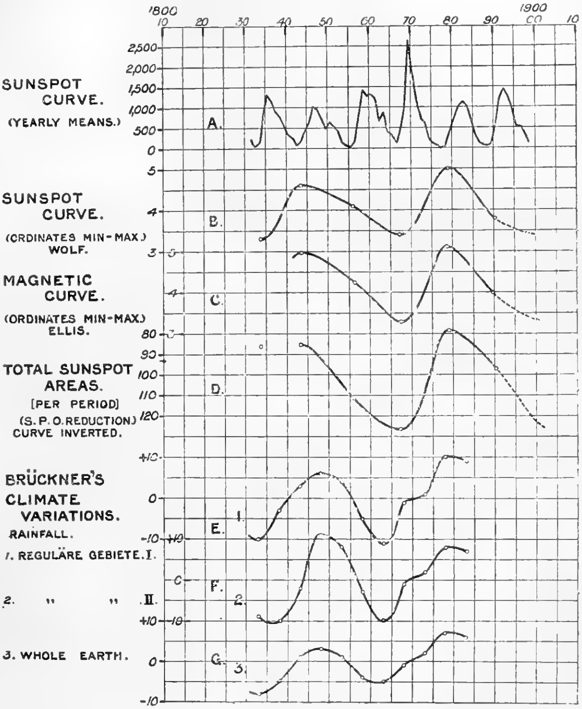

FIG. 2.

There seems little doubt that, during the interval of time covered by the present sunspot discussion, the meteorological phenomena, number of auroræ, and magnetic storms show secular variations of a period of about thirty-five years, the epochs of which harmonise with those of the secular variations of sunspots. As we are now beginning to approach another maximum of sunspots which should correspond both in intensity and in time of occurrence after the epoch of the present minimum with that of 1870·8, it will be interesting to observe whether all the solar, meteorological and magnetical phenomena of that period will be repeated.

WILLIAM J. S. LOCKYER.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—At a convocation on June 18, the honorary degree of D.C.L. was conferred upon Mr. Cornelius N. Dalton, C.B., master of the Drapers' Company.

On the same day, the new Radcliffe Library building, which has been erected by the Drapers' Company at a cost of about 21,000*l.*, was formally handed over to the University in the presence of a large number of members of the Company and of the University.

CAMBRIDGE.—Prof. Newton, F.R.S., has been appointed a manager of the Balfour fund for the ensuing five years.

The Harkness scholarship in geology has been awarded to W. G. Fearnsides, Sidney, and the Wiltshire prize in palæontology to E. R. Watson, Jesus.

Thirty-seven names appear in the first class of the natural sciences tripos, part i., and ten in the first class of part ii. Four are the names of Newnham students.

The work of Mr. Hugh Ramage, advanced student of St. John's, on spectrum analysis, has been pronounced "of distinction" as a record of original research and as a qualification for the B.A. degree.

MR. CHAMBERLAIN has addressed a letter to the Lord Mayor of Birmingham, on behalf of the council of the Birmingham University, suggesting that a rate should be made in aid of the University. The amount subscribed for the establishment of the University is 400,000*l.*, but a large proportion of this will be absorbed in the erection and equipment of buildings necessary for instruction and research. The increased cost of maintenance involved in the scheme cannot be wholly provided from the fees of students, and it is on this account that an appeal is made for assistance. In support of the appeal the council refer to the precedents already established in similar cases, notably in connection with University colleges founded in other provincial towns. Thus the corporation of Nottingham contributes 7380*l.* a year to Nottingham College, Sheffield gives nearly 6000*l.* a year to the Firth College, the corporation of Leeds 1500*l.* a year, the corporation of Manchester 1100*l.*, and the corporation of Liverpool, besides a grant of land of the value of 30,000*l.*, an annual contribution of 1800*l.* Other contributions of a substantial character have been made in many cases by the county authorities; and it is hoped that if Birmingham will set the example the counties which will derive benefit from the extension now proposed of University work in the Midlands will not be unwilling to take their share of responsibility. A rate of ½d. in the pound would in Birmingham provide an annual contribution of about 5000*l.*, which would justify the council of the University in proceeding immediately with the new departments, the necessity for which, in view of the increasing pressure of foreign competition, is daily becoming more urgent.

AT the meeting of the General Medical Council last week a prolonged discussion occurred upon the regulations for the first year of medical study, and the educational institutions which should be accepted as fit and proper places for passing one year of the obligatory five years of professional study. The main question was whether a year at a grammar school, or similar educational establishment where general subjects as well as science is taught, should count as one year of medical training in the five years' curriculum. For one side it was stated that the laboratories at some of the institutions recognised by the Council were as well equipped as those of some medical schools. It was also urged that chemistry, physics and biology might be considered as an extension of the preliminary education required before medical study, properly so called, can be commenced, and that the medical curriculum required should be four years taken subsequently to passing an examination in them. If this view is accepted at the next meeting of the Council, it would seem, says the *British Medical Journal*, that the whole question of the places at which instruction may be obtained may disappear, for it will be argued that, provided the necessary knowledge is obtained and tested by adequate examination, it will no longer be the business of the Council to concern itself how or where it is obtained, any more than in the case of Latin or any other subject of preliminary education. The subject has been referred to the Education Committee of the Council, and judging from the views expressed during the debate it seems that there are not a few members who think that scientific education is now provided for so well at schools not strictly medical that one year of professional study may properly be carried out in such institutions.

SCIENTIFIC SERIAL.

Bulletin of the American Mathematical Society, May.—The three papers in the present number were all read at the February meeting of the Society. Non-oscillatory linear differential equations of the second order, by Prof. Bôcher, has for its object the deduction of certain conditions that the equation

$$\frac{d^2y}{dx^2} + \frac{pdy}{dx} + qy = 0$$

should be non-oscillatory. This equation is said to be oscillatory or non-oscillatory in the interval $a \leqq x \leqq b$, according as it does or does not have at least one solution (not identically zero) which vanishes more than once in this interval. Conditions have been obtained by Picard, but the method used in the present paper is not only entirely different, but yields, in addition, other results not given by Picard's method. In the author's opinion it is also less artificial.—Concerning real and complex continuous groups, by Prof. L. E. Dickson, is an attempt to illustrate certain differences and analogies between related real and complex continuous groups. Lie's theory has been developed chiefly for the latter groups, the modifications necessary for real groups being treated quite briefly.—On holomorphisms and primitive roots, by Dr. G. A. Miller, is devoted to some additional developments along the earlier line adopted by the author in a previous paper (*Bulletin*, vol. vi. p. 337, 1900).—The following works are reviewed, viz.: "Einleitung in die Theorie der Besselschen Funktionen" (Prof. J. H. Graf and Dr. E. Gubler), by Dr. V. Snyder; and "Leçons sur la théorie des Formes et la Géométrie analytique supérieure" (H. Andoyer), by H. S. White.—The usual points of interest, collegiate and other announcements, and list of recent publications are well to the front.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 23.—"On the Presence of a Glycolytic Enzyme in Muscle." By Sir Lauder Brunton, F.R.S., and Herbert Rhodes.

For some time physiologists have suspected the presence of some enzyme in muscle which has the power of breaking up the sugar with which the muscle is supplied through the blood, and converting this food into energy with the formation of simpler oxidised bodies. The presence of such an enzyme in fresh muscle juice was apparently proved by Brunton in 1873, but the method of experiment used was open to criticism.

Previous to the present paper the materials used had not been rendered free from possible fermentative organisms, so that it could not be definitely said that the marked glycolytic action exhibited by the juice was not due to some fermenting fungus or bacterial contamination.

The muscle juice was obtained from the yet living flesh of a sheep by comminution with sand and hydraulic expression.

In these later experiments the muscle juice was rendered sterile by filtration through a Pasteur Chamberland candle, the other fluids boiled for considerable periods, and the apparatus disinfected by steam.

Two flasks were prepared, each containing fresh sterile muscle juice and sugar solution; in one the juice was boiled previously to adding the sugar solution.

After incubation at body temperature the sugar in each flask was estimated quantitatively, the result showing a very marked diminution in the percentage of sugar in the flask containing unboiled juice.

Thus it was shown that a substance exists in fresh muscle which has the power of breaking up the sugar molecule, and this substance partakes of the nature of a glycolytic enzyme.

Although an attempt had been made to isolate the enzyme, it is of such a delicate nature that the isolating procedure adopted destroyed its fermenting power.

Physical Society, June 14.—Prof. S. P. Thompson, F.R.S., president, in the chair.—A paper on Herr Jahn's measurements of the electromotive force of concentration cells was read by Dr. Lehfeldt. Prof. D. Jahn has recently published measurements of E.M.F.'s of concentration cells, from which he has endeavoured to show that the law of dilution is applicable to strong solutions. The author points out that his conclusions are based on argument in a circle because Ostwald's law is assumed in the formula used by Jahn for calculating degrees of concentration. The formulæ of Nernst and Arrhenius do not yield consistent results, and it is suggested that the former is suitable for calculating concentrations and the latter for calculating osmotic pressures.—A paper on the mechanism of radiation was read by Mr. J. H. Jeans. This paper contains an attempt to obtain answers to two questions:—(1) What inferences can be drawn as to the mechanism by which radiation is emitted from an examination of the formula of physical optics? and (2) Is it possible, with the help of these inferences, to frame any conception of matter which will give a consistent account of the various optical phenomena? Starting with general spectroscopy, the author has written down the radiation due to a single rotating molecule vibrating harmonically. The effect of a number of molecules is deduced, and it is shown that the condition that the continuous banded spectrum shall be absent is that either the period of rotation must be large compared with the period of vibration or the radiation from a molecule must be spherically symmetrical. Passing on to dispersion, even if the radiation is continuous between collisions, there will be a discontinuity at every collision and the train of waves will be no longer regular. It is customary to assume that the vibrations of a dispersing medium are sympathetic with the irregular incident light. The author has calculated the ratio between forced and free vibrations in a prism or grating, and finds that if the dispersion is to be regular the vibrations must be only slightly influenced by collisions, and this requires, as in the former case, that either the period of rotation is large compared with the period of vibration, or the radiation is spherically symmetrical. As this is not the case with molecules the author thinks that the line spectrum is emitted by atoms, that these atoms must be dissociated and that the shape of these atoms is one of spherical symmetry. It is shown that if an atom is an electromagnetic system, similar to a planetary system, then the periods of such an atom would not be fixed and there would be no reason for a line spectrum. The normal atom is therefore regarded as an electrostatic system, with some law of force, other than the inverse square law, holding at interionic distances. Such an atom when at rest would give a pure line spectrum. Rotation of such an atom causes the lines of the spectrum to shift towards the red, and as the rotation is different for different atoms the lines will not only be shifted, but broadened. To calculate the periods of vibration of an atom the author has assumed it to consist of an infinitely great number of infinitely small ions. The spectrum of this consists of a collection of spectrum series each possessing a definite head and capable of explaining doublets, triplets, &c. It is shown that under the action of a magnetic field a line may separate out into approximately equidistant lines, the central lines maintaining its position. In conclusion, the author points to many other physical phenomena which can be explained by the theory described.—The chairman then exhibited some specimens of Jena glass. In describing these, reference was made to a diagram showing the refractive index, dispersion between the C and F lines, and the reciprocal of the dispersive power of any piece of glass. For this latter quantity the symbol "ν" is used, and it was suggested to call it the achromatic refractivity of the glass. The introduction of barium increases the deviation, but leaves the dispersion unaltered. It is possible now to get crown glass with a higher refractive index than flint glass, and this makes it possible to construct an achromatic lens which will also give a flat field. It is usual in making achromatic objectives to make them accurately achromatic for the red and violet rays. A better effect can be obtained by having approximate achromatism throughout the length of the spectrum. This is achieved by matching the irrationality of one glass by means of another and then constructing an achromatic pair with these two glasses. "Telescope crown" and "telescope flint" are two glasses which give similar spectra and approximate achromatism from the red to the violet.—The Society then adjourned until June 28, when the meeting will be held, by the invitation of Prof. W. G. Adams, in the laboratory of King's College.

Geological Society, June 5.—Mr. J. J. H. Teall, V.P.R.S., president, in the chair.—On the passage of a seam of coal into a seam of dolomite, by Aubrey Strahan. The author was informed by Mr. N. R. Griffith in 1900 that the seven-feet seam of the Wirral Colliery had been found to pass into stone of an unusual character. For a distance of 1600 yards from the shaft this seam was good, and about 4 feet thick. A little farther in bands of stone from 1 to 10 inches thick made their appearance in it, and, gradually increasing in thickness, these bands eventually constituted the whole seam, the last traces of workable coal disappearing at 250 yards from the point where the change first began. The boundary of the barren area has been found for a distance of 1480 yards, and it runs north and south. The stone is at first black, but after weathering it becomes grey, and displays curious structures, among which are pisolitic, or mammillated structures, the intervening spaces being filled with coaly matter. One specimen displays woody tissue filled with dolomite. Analyses by Dr. W. Pollard yield from 18·5 to 13 per cent. of magnesia. The phenomena are not those of a "wash-out," as there is no sign of erosion, but there is proof that the dolomite was formed in almost motionless water, and the conditions appear to have been those under which a tufa would form. It appears to have been formed on a spot to which clastic material scarcely gained access, and which was reached even by vegetable matter in scant quantity and in a finely divided condition.—On some landslips in boulder-clay near Scarborough, by Horace W. Monckton.

EDINBURGH.

Royal Society, June 3.—Dr. Hepburn in the chair.—In a paper on binary fission in the life-history of Ciliata, Dr. J. Y. Simpson gave excerpts from statistics of two months' cultures of *Paramoecium caudatum* showing that under the most natural circumstances attainable binary fission does not proceed with that mechanical regularity that Maupas asserted. Further, experimenting with cultures of *Stylossichia pustulata*, he found with Joukowsky as against Maupas that degeneration after continued division shows itself in a general listlessness, in ebbing of vital energy and decrease of size, rather than in definite nuclear disorganisation, but on the other hand, with Maupas as against Joukowsky, that it is not possible to induce conjugation before puberty. Some Paramœcium monstrosities were described, and microphotographs of living *P. aurelia* and *P. caudatum* were shown, establishing the existence of the two species which had recently been called in question.—Dr. E. G. Coker communicated a paper in which were described his various forms of apparatus for measuring strain and applying stress, together with a great many measurements made by means of them. The aim in all was to have the different parts of the measuring apparatus attached to the specimen itself; and probably the most ingenious arrangement was the device for applying and measuring the effects of combined bending and twisting. Another combination was longitudinal stretch and twist. The influence of the one kind of strain upon the elastic relations of the other kind were carefully investigated, especially in the neighbourhood of the yield-point. The behaviour of iron and steel bars when subjected to strain cycles was also studied, and other important questions connected with hysteresis, fatigue and recovery in time.—Mr. W. E. Collinge communicated a paper on the anatomy of a collection of slugs from North-west Borneo, the general results being as follows. The *Damayantia plecta* of Issel was re-described and some notes given on the anatomy of the new species, *D. carinata*. Two new genera were established, viz., Wiegmannia and Isselentia, with five new species. The *Damayantia smithi* (Cllge. and Godw., Auct.) was shown on anatomical grounds to belong to the genus Collingia. Finally two new species of Veronicella and one of Onchidium were described, and a check list of the known species from Borneo was given.

PARIS.

Academy of Sciences, June 10.—M. Fouqué in the chair.—Studies in neutralisation. On the titration of acids and alkalis of complex function with the aid of colouring matters, by M. Berthelot. A study of the behaviour of some amino-acids towards indicators. Of these glycocoll and leucine are acid to phenolphthalein, alkaline to methyl-orange, and neutral to litmus. The three aminobenzoic acids have a clearly acid function except towards methyl-orange.—The phenomena of calorific convection and the cooling power of liquids, by M. J. Boussinesq.—On the series of Bernoulli, by M. G. Mittag-Leffler.—On the Eulerian incomplete integrals of the second species and the indefinite integrals of the preceding functions, by M. E. Vallier.—On the region of convergence of an infinite integral, by M. E. Phragmén.—On a remarkable invariant of certain transformations realised by self-recording apparatus, by M. Rabut.—The laws of Gay-Lussac and the dissociation of gaseous compounds, by M. A. Ponsot. It is usually held that the law of Avogadro is an approximate law which tends to become more exact as the volume increases. According to the investigation in the present paper this is not the case.—The vibrations produced in a wire with an influence machine, by M. D. Negreano. If an insulated stretched wire contained in a tube is connected with one of the poles of a Wimshurst influence machine, transverse vibrations are set up in the wire, and if viewed in the dark, portions of the wire become visible.—On an electrolytic rectifier, by M. Ch. Pollak. A description of the conditions under which it is possible to use aluminium electrodes in an electrolytic apparatus for rectifying alternating currents, together with the precautions necessary in forming the plates.—On an electrical grisoumeter, by M. G. Léon. Two small platinum wires forming two of the arms of a Wheatstone's bridge are kept at a red heat by a small battery of accumulators, one of the wires being placed in pure air and the other in the atmosphere containing methane. The presence of the methane causes a rise in the temperature of the latter wire which results in a deflection of the galvanometer, this deflection being proportional to the amount of marsh gas present.—On the experimental verification of a law of chemical mechanics, by M. H. Pélabon. The reaction between hydrogen and mercuric sulphide has been experimentally studied and the results applied to the verification of the formula $p_1p_2/p_3p_4=f(\text{T})$.—The action of a metallic hydrate upon a salt of another metal. Basic salts with two metals, by M. A. Recoura. Results of experiments upon the reactions between copper hydrate upon solutions of zinc sulphate, and of the sulphates of cadmium, manganese, cobalt, nickel and copper.—On the imidodithiocarbonic esters, $RN:C(SR')_2$, by M. Marcel Delépine.—On the active erythritols, by MM. L. Maquenne and G. Bertrand. Measurements of the rotatory power of the two erythritols in water and in alcohol, and description of the preparation of the tetra-acetyl, benzoyl and valeryl derivatives, and also of the oxidation products.—Study of a densimeter for the determination of the baking value of wheaten flour, by M. E. Fleurent.—Analysis of some travertines from the Vichy basin, by MM. C. Girard and F. Bordas.—On the olivine gabbro from Kosswinsky-Kamen (Ural), by MM. L. Duparc and F. Pearce.—On the function of the eustatic oscillations of the level of the base in the formation of systems of terraces in some valleys, by M. D. Lamothe.—On the morphology of the sexual elements in some species of Stylorhynchus by M. Louis Léger.—On the constant presence of a gregariniform stage in the cycle of evolution of hematozoa of malaria, by M. A. Billet.—New observations on the parthenogenesis of the sea urchin, by M. G. Viguier.—On the use of silicotungstic acid as a reagent for the alkaloids of urine. The variations of alkaloidal nitrogen, by M. H. Guillemard. The ratio of the alkaloidal nitrogen to the total nitrogen existing in urine varies to some extent with the food, but in certain febrile diseases this ratio undergoes enormous variations, there being in the latter case a considerable increase in both the absolute and relative quantities of the alkaloids eliminated.—On the otoliths of the frog, by M. Marage.—On a new method of examination for the typhoid bacillus, by M. R. Cambier. It is found that if a sterile broth contained in a tube of biscuit porcelain, which latter dips also into sterile broth, is inoculated with the typhoid bacillus, in the course of its growth the bacillus is able to make its way through the porcelain, even although this same porcelain is quite capable of filtering off the bacillus in the ordinary way. It was found that the more actively motile the bacillus the more easily was the filter penetrated in this way. Several other species of bacilli were found to be capable of traversing the walls of the filter in a similar way, but none of the species examined up to the present pass through so rapidly as the typhoid bacillus. On the basis of these observations the author founds a method of determining the presence of this bacillus in potable water, and he has been able to recognise the Ebert bacillus in water from the Seine and the Marne and also in the waters from certain springs.—Six months' meteorological observations at Quito, by M. F. Gonnessiat.

DIARY OF SOCIETIES.

THURSDAY, JUNE 20.

ROYAL SOCIETY, at 4.30.—The Nature and Origin of the Poison of *Lotus arabicus*: W. R. Dunstan, F.R.S., and T. A. Henry.—(1) On the Mathematical Theory of Errors of Judgment, with Special Reference to the Personal Equation; (2) Mathematical Contributions to the Theory of Evolution. X. Supplement to a Memoir on Skew Variation: Prof. K. Pearson, F.R.S.—On the Application of Maxwell's Curves to Three-Colour Work, with Especial Reference to the Nature of the Inks to be employed, and to the Determination of the Suitable Light-filters: Dr. R. S. Clay.—On the Structure and Affinities of *Dipteris*, with Notes on the Geological History of the Dipteridinæ: A. C. Seward, F.R.S., and Miss E. Dale.—(1) Further Observations on Nova Persei, No. 3; (2) Total Eclipse of the Sun, May 28, 1900: Account of the Observations made by the Solar Physics Observatory Eclipse Expedition and the Officers and Men of H.M.S. *Theseus*, at Santa Pola, Spain: Sir Norman Lockyer, K.C.B., F.R.S.—The Mechanism of the Electric Arc: Mrs. H. Ayrton.—And other Papers.

LINNEAN SOCIETY, at 8.—On the Freshwater Algæ of Ceylon: W. West and G. S. West.—On Coprophilous Fungi: George Massee and E. Salmon.—Revision of the Genus Hypericophyllum, Steetz, with Notes on certain Genera with which it has been confused: N. E. Brown.

N. Collie, F.R.S.—Two New Substances in Lemon Oil: H. E. Burgess.

MONDAY, JUNE 24.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Belgian Antarctic Expedition: Henryk Arçtowski.

CONTENTS.

THURSDAY, JUNE 27, 1901.

STUDIES IN COMPARATIVE RELIGION.

The Golden Bough: a Study in Magic and Religion. By J. G. Frazer, D.C.L., LL.D., Litt.D. Second Edition. Revised and enlarged. Three volumes. Vol. i., pp. xxviii + 467; vol. ii., pp. x + 471; vol. iii., pp. x + 490. (London: Macmillan and Co., Ltd., 1900.) Price 30*s*. net.

WITHIN recent years few books have exercised more influence on the study of comparative religion than Mr. Frazer's "Golden Bough," the first edition of which appeared in 1890. Working in the main on the lines laid down by Prof. E. B. Tylor, he applied the results obtained from a prolonged study of the beliefs and practices of primitive races to explain the meaning and origin of a strange rule of an ancient Italian priesthood. Near the lake of Nemi in the Alban hills, at some distance from the ancient town of Aricia, stood a grove and sanctuary sacred to Diana, and the strange rule of the priesthood attached to the grove finds no parallel in classical antiquity. The priest, who bore the title of "King of the Wood," watched night and day with a drawn sword, always ready to defend his life against the attack of a possible assailant. A candidate for the priesthood had first to break off a bough from a certain tree in the wood, and, if successful, he was entitled to fight the priest in single combat; should he slay the priest he reigned in his stead until he in his turn was slain. Mr. Frazer's book takes its title from the tradition that the branch guarded by the priest was the Golden Bough which Æneas plucked before he attempted his journey to the realm of the dead. Put briefly, Mr. Frazer's explanation of the rule amounts to this: the King of the Wood was an incarnation of the tree-spirit, or spirit of vegetation, which was also inherent in the Golden Bough, or mistletoe, growing on the tree, probably an oak, in the Arician grove. The only way of preserving the tree-spirit from decay necessitated the priest's violent death; the divine life by this means was transferred to a suitable successor—that is to say, to the stronger man who should slay him. But in his character of a tree-spirit, the priest's life was bound up with that of the mistletoe on the tree; hence it was necessary for the slayer first to break the Golden Bough. The exposition of this theory furnished the thread on which Mr. Frazer skilfully arranged a series of exhaustive essays dealing with many phases of primitive superstition and belief.

In our review of the first edition of the book (see NATURE, September 25, 1890, vol. xlii. pp. 513 ff.) we described in detail the various steps in Mr. Frazer's argument, and we shall not, therefore, go over the same ground again, but rather confine ourselves to noticing the most important additions which Mr. Frazer has incorporated. The book has been considerably expanded, for it now consists of three instead of two volumes, and a rather smaller type has been used. The system of arrangement and the division into four chapters has been retained, but there are few parts of the work to which considerable additions have not been made. During the ten years that have elapsed since the publication of the first edition, most valuable researches have been carried on by Messrs. Spencer and Gillen in Central Australia, by Mr. Skeat in the Malay Peninsula, by Mr. van der Toorn in Sumatra, and by the late Miss Kingsley in West Africa, to mention but a few names among the growing band of practical anthropologists; and the store of new material thus collected has furnished Mr. Frazer with a host of fresh examples to illustrate his theory. Great advances have also been made in our knowledge of the ancient Egyptian and Babylonian religions, and Mr. Frazer has availed himself of the recently published works on these subjects. Such additions have considerably increased the subsidiary and illustrative portions of the book, but they only affect the main argument in so far as they furnish additional proofs and instances. Two sections, however, have not only been expanded, but have been recast and rewritten, and with these we propose to deal in greater detail. In the first edition a short section of a few pages was devoted to a description of primitive man and his conception of things supernatural; in the second edition this has been expanded into a regular treatise, in which Mr. Frazer for the first time formulates his theory of the relation of magic to religion. Again, in the first edition the author only hinted at the bearing which his researches might have upon some of the central tenets of the Christian religion; in the second edition he has worked out his theory in detail.

Speaking broadly, Mr. Frazer has come into line with the majority of anthropologists and students of religion in regarding magic and religion as totally distinct from one another, the former representing a lower intellectual stratum which has probably everywhere preceded the latter. When writing his first edition, Mr. Frazer tells us, he did not accurately define, even to himself, his notion of religion, and he was disposed to class magic loosely under it as one of its lower forms. He has now framed his definition of religion, not by collecting the opinions of the learned on the subject, but directly from his own study of the facts. Mr. Frazer's position among contemporary writers would ensure for any view he might propound the most careful study and consideration; we note with the greater pleasure, therefore, that his mature opinion on the relation of magic to religion does not necessitate the recasting of the theory at present in the field. In his opinion the movement of man's thought has, on the whole, been from magic, through religion, to science. In magic man depends on his own strength to meet the difficulties and dangers that beset him. He believes in an established order of nature which by certain actions of his own (*i.e.* magic) he can manipulate for his own ends. When he discovers his mistake and finds he cannot control nature as he believed, he ceases to rely on his own unaided efforts and ascribes to certain great invisible beings behind the veil of nature the far-reaching powers which he once arrogated to himself. Thus magic is gradually superseded by religion, and natural phenomena are believed to be regulated by beings who are like men in kind and are swayed by human passions, but are endowed by powers vastly superior to his. As time goes on this explanation in its turn proves unsatisfactory. The longer nature is studied the succession of natural events appears less and less variable and irregular.

"The keener minds," writes Mr. Frazer, "still pressing forward to a deeper solution of the mysteries of the universe, come to reject the religious theory of nature as inadequate, and to revert in a measure to the older standpoint of magic by postulating explicitly what in magic had only been implicitly assumed, to wit, an inflexible regularity in the order of natural events, which, if carefully observed, enables us to foresee their course with certainty and to act accordingly. In short, religion, regarded as an explanation of nature, is displaced by science."

We have here a sane and consistent theory of the progress of human thought, and we wish we had space to quote at greater length; for further details we must, however, refer the reader to the book itself.

In passing to the section which treats of "The Saturnalia and Kindred Festivals" we come upon more debatable ground. Here Mr. Frazer has expanded his theory of the general prevalence of the custom of killing a human god, so as to include, and to some extent explain, the crucifixion of Christ. We may say at once that we hold no brief for the orthodox view with regard to that event, and, if the evidence tended to prove that the crucifixion, with the mockery which preceded it, was not a punishment specially devised for Christ but merely the fate which annually befell a malefactor who played the part of a mock king during a sort of Saturnalia, there would be no reason, so far as we are concerned, why the theory should not be accepted. Mr. Andrew Lang, in the character of a champion of orthodoxy, has already made an onslaught upon Mr. Frazer, and we have no intention of following his example or of adopting his methods of controversy. But to our thinking Mr. Frazer has in this portion of his book been induced to abandon his excellent practice of following his evidence, and has considerably outrun it.

In his explanation of the rule of the Arician priesthood Mr. Frazer infers that at an earlier period one of the priests had probably been slain every year in the character of an incarnate deity. In his first edition the only parallel case he could cite was the custom of killing a human god annually in ancient Mexico. Now from a narrative of the martyrdom of St. Dasius, published by Prof. Cumont in 1897, it would seem that at the celebration of the Saturnalia the King, or Lord of Misrule, had not always been a mere clown, but that at one time it was the custom, after a riotous rule of thirty days, that he should put himself to death. This new piece of evidence Mr. Frazer justly claims as a striking confirmation of his theory with regard to the Arician priesthood, but it does not prove, or render likely, the extensive prevalence in the East of the custom of annually killing a human god which his theory of the crucifixion presupposes.

There is some evidence that during the late period of Babylonian history, after the Persian conquest, an annual feast took place in Babylon termed the Sacæa, which resembled the Saturnalia in that masters and servants changed places and a mock king presided over the revels. The evidence for the festival consists of a quotation by Athenæus from Berosus, while Dio Chrysostom, quoting probably from Berosus or Ctesias, adds the additional detail that the mock king was subsequently executed. Dr. Bruno Meissner has conjectured that the Sacæa may have corresponded to Zag-muk, the Babylonian festival of the New Year. We still know very little about the manner in which Zag-muk was celebrated, but, in spite of a difficulty of dates, it is possible that Sacæa was a late form of that festival. Moreover, the Jewish feast of Purim, the earliest references to which occur in Esther and the second book of Maccabees, was probably borrowed by the Jews during their captivity, and may well have been taken from the Babylonian Zag-muk, as Prof. Zimmern, of Leipzig, has suggested. There is no doubt that both Zag-muk and Purim were celebrated with feasting and revelry; but Mr. Frazer goes further, and would find in the account of the institution of Purim in the book of Esther traces of the slaying of a mock king such as, according to Dio Chrysostom, took place at the Sacæa.

It will be remembered that the book of Esther describes the rivalry between Haman, the vizier of Ahasuerus (probably a corruption of *Khshayārsha*, *i.e.*, Xerxes), King of Persia, and the Jew Mordecai; it relates how the Jews, when doomed to destruction through Haman's influence, were delivered by the Queen Esther and her uncle Mordecai, and how Haman perished on the gallows he had prepared for his rival. Prof. Jensen, of Marburg, has recently formulated a theory that the names Haman and Vashti are those of an Elamite god and goddess, and that Mordecai and Esther are the Babylonian deities Marduk and Ishtar; and, further, that the story reflects an antagonism between the gods of Elam and the gods of Babylon. Mr. Frazer accepts the identifications, and in the story of the death of Haman on the gallows sees a further reflection of the custom of slaying a man in the character of a god. He thinks that such human sacrifice formed part of the original rites of the feast of Purim, and was probably derived from some similar rite among the Babylonians. In the burning of effigies of Haman at the feast of Purim by the later Jews he sees a survival of this human sacrifice. The rite he explains, on lines already familiar to his readers, as a magical ceremony intended to ensure the revival and reproduction of life in spring.

In such ceremonies elsewhere the man-god dies only a mimic death and then rises again, or else he was actually slain and was thought to live in the person of a successor who took his place. In the Esther story Mr. Frazer suggests that Mordecai represents the second temporary king, who, on the death of his predecessor, was invested with the royal insignia and exhibited to the people as the god come to life again. In Vashti and Esther he sees the divine consorts of the mock kings during their brief periods of rule. In this way he explains the story of the struggle between Haman and Vashti, on the one side, and their doubles, Mordecai and Esther, on the other:

"Both pairs stood for the fertility of plants and perhaps of animals; but the one pair embodied the failing energies of the past, the other the vigorous and growing energies of the coming year."

In the original form of the rite from which Mr. Frazer supposes the feast of Purim to be derived, he suggests that the Babylonian king was the actual victim who was put to death each year, but that subsequently a substitute was always found in one of his sons, or a slave, or a malefactor. His period of rule was also curtailed from a year to a few days each year.

Now the details of the crucifixion present some resemblance to the treatment of the mock king in the Sacæa. Both victims were clothed in fine raiment and crowned as kings, and afterwards scourged aud crucified. This, Mr. Frazer thinks, is not a chance resemblance. The Jewish feast of Purim may have been derived from Zag-muk, which in turn may possibly be identified with the Sacæa; and he suggests that the Jews in the time of Christ may have every year at the feast of Purim compelled a condemned criminal to play the part of Haman and be put to death, in the same way as their later descendants destroyed effigies of him. Briefly, Mr. Frazer's theory is that Christ was put to death as one of these yearly victims. That the crucifixion took place at Passover, *i.e.* a month after the Feast of Purim, he thinks may be explained by supposing that Christian tradition for purposes of edification shifted the date of the crucifixion from Purim in order to make the sacrifice coincide with the annual sacrifice of the Passover lamb. He offers the alternative suggestions that the Jews may have sometimes celebrated Purim at about the time of the Passover (*i.e.* in Nisan) in consequence of its derivation from the Babylonian Zag-muk, which was held in Nisan; or, finally, the Jews may have spared the victim of the feast of Purim for one month, when his death would occur at Passover. Thus, according to Mr. Frazer, Christ was crucified and Barabbas was released as part of the passion-play performed each year by the Jews at Purim. They took the parts of Haman and Mordecai respectively, and at the end of the performance the one who played Haman was crucified, and the other, who personated Mordecai, was allowed to go free. Following out his theory, Mr. Frazer suggests that the name Barabbas, "Son of the Father," was not the name of an individual, but was the title given to one or both of the actors in the play. Similarly, the description of Christ's triumphal ride into Jerusalem before his death, and the account of the raid he made afterwards upon the stalls of the money-changers in the temple, he thinks may perhaps be traced to those arbitrary rights over property which it has been customary to accord to such temporary kings during their brief period of rule. The hero of the drama, in fact, may have been "no more than a moral teacher whom the fortunate accident of his execution invested with a crown not merely of a martyr, but of a god."

Such is Mr. Frazer's theory, and we confess to feeling that, unlike the rest of his book, this section contains a great deal of theory and very little evidence. That the rites of the late Sacæa were identical with those of the earlier Babylonian Zag-muk is pure assumption; and that a Babylonian king was at one time annually slain is unsupported by any evidence, whereas had this been the case the custom must have left some trace in the Babylonian literature. Prof. Jensen's identification of the principal personages mentioned in Esther with Elamite and Babylonian deities is, to say the least, a little fanciful, and still more fanciful is Mr. Frazer's improvement on his theory; it is hard to recognise in the story a reflection of a passion play. Finally, the question of dates is a real difficulty of which not one of Mr. Frazer's alternative theories successfully disposes. After careful study we think it easier to explain the resemblance of Christ's crucifixion to the rites of the Sacæa as the result of coincidence rather than to accept the artificial theory we have summarised. Moreover, with a strange absence of logic Mr. Frazer claims that his theory sheds "fresh light on some of the causes which contributed to the remarkably rapid diffusion of Christianity in Asia Minor"; as a matter of fact, it does the reverse. The political significance of Christ's martyrdom and the prominence it consequently gave his following form the simplest explanation of the rapid spread of Christianity. The more ordinary and normal the crucifixion is represented the harder it is to understand the problem; Mr. Frazer's theory reduces the crucifixion to an annual event.

We have dealt in some detail with the two chief novelties of the second edition of the work; our criticism of one theory, however, should not be taken as detracting in any way from the general value of the book, which will always form a storehouse of facts for the student of religion, and which will surely influence for many years the work of those who concern themselves with that wide and attractive field of study.

THE ISLAND OF CELEBES.

Über die geologische Geschichte der Insel Celebes auf Grund der Thierverbreitung. Von Dr. Paul Sarasin und Dr. Fritz Sarasin. Pp. vi + 169; 15 plates. (Wiesbaden: Kreidel, 1901.)

THE island of Celebes, as is well known, is comparable in a metaphorical sense to one of the floating islands of antiquity; it has not definitely come to rest in either the Australian or the Oriental region. By some authorities its marsupial inhabitants are held to outweigh in importance its likeness in other respects to the islands of the Malayan archipelago, and it is associated with Mr. Sclater's Australian region; others, again, place it as definitely with the Oriental region; while its anomalous and intermediate character has led not a few to fatal hesitation and to consequent abandonment of the problem. The authors of the volume before us dismiss at once, and with some brusqueness, all consideration of this matter. The chief problem of geographical distribution is for them not "whether Celebes belongs to the Oriental or to the Australian region, but what are the land connections, and of what epoch, which must be assumed to account for the condition of its fauna to-day?" This attitude of mind shows a healthy reaction against the elaborate method adopted by many zoogeographers of late years. The detailed planning and plotting out of the globe into a complicated series of regions, subregions and provinces is not, in the opinion of the present writer, of great usefulness save in so far as it allows of a rapid and perhaps graphic method of indicating the range of a particular animal. The two authors proceed further to observe that it is better to select, for the purposes of such problems as are presented by Celebes, species and not genera of animals; and this on the perfectly reasonable grounds that while the limits of genera are most diversely regarded, there is not, at least, so much difference of opinion as to the limits of a species. They are thus a safer indication of both likenesses and differences in two faunas. Mr. Sclater, some years ago, proposed the term of "lipotype" to express a negative state of affairs; a genus or species which was, as it were, unaccountably absent from a given region was thus denominated.

There is no doubt that this expression was wanted and that it did emphasise important zoogeographical fact. Nevertheless, it must be used with care, especially with regard to smaller and less conspicuous creatures. The Drs. Sarasin instance the case of the land planarians of Celebes. It was written so recently as 1891 that not a single species of this group of Platyhelminthes had been found in Celebes. Now we are acquainted with quite a number of forms, so much so that Celebes is the second richest island of the whole Malayan archipelago in these worms. We are glad to notice that the authors carefully distinguish between artificial introduction of species and introduction by natural means. To this matter attention has not, perhaps, been sufficiently drawn, and the wide range of many small creatures which has been used as an argument for their antiquity and has been generally made use of by the zoogeographer has not always the real value that has been attached to it. After due sifting of such fraudulent claimants to indigeneity the authors are, roughly speaking, disposed to do what has been mocked at—to demand a continent to explain the range of a beetle. Avoiding exaggeration, we can assert that the authors are not at all impressed by the floating log *deus ex machinâ;* they think that similar inhabitants on opposite sides of a sea generally imply a former land connection.

It will be noted from the few observations made that the authors preface their detailed consideration of the fauna of Celebes and neighbouring islands with some remarks of a general nature, which might perhaps have been rather more expanded if the work had not been of so special a character. The animal groups made use of by the authors are chiefly the molluscs, reptiles and amphibians; birds, mammals and land planarians are not neglected. The fact that there are more peculiar species of molluscs than of reptiles and amphibians is commented upon; this the authors attribute to the greater mobility of the two vertebrate groups. In discussing all zoological characteristics of Celebes it must be borne in mind, as is duly pointed out on p. 128, that the island itself first rose from the waves after Eocene times, for a great mass of the solid rock of which it is built is Eocene chalk. The view of its subsequent history which the fauna appears to indicate is that it first showed itself above the water in the Miocene and that during the Pliocene it was in connection with neighbouring islands, from which it became subsequently and at different times detached. It is justly described, therefore, as a "fragment of a Miocene continent." One important exception, however, exists to the statement that Celebes has been in the past in connection with the other islands of the surrounding seas. The authors point out that there is not a single species of animal known to be common to Celebes and Borneo and not at the same time found in some of the other islands; this, as is justly inferred, seems to indicate that Celebes can never have been connected by a land bridge with Borneo directly, though, of course, it probably was indirectly by way of Java, on the one hand, and possibly (though the authors think not) the Philippines on the other. The Macassar strait thus represents a tract of ocean which has been water before and since the appearance of Celebes upon the earth's surface. On the other hand, the supposed deep channel on the south intervening between Bali and Lombok is, as it appears from Prof. Max Weber's soundings, to be given up, since the greatest depth then ascertained to exist was merely 312 metres. This volume is of extreme interest as a detailed attempt to reconstruct from a comparison of faunas the past geological history of a group of islands. It is abundantly illustrated with maps, and concludes with an historical review of the literature of the subject and a list of memoirs and books.

F. E. B.

ENGINEERING EDUCATION.

Proceedings of the Eighth Annual Meeting of the Society for the Promotion of Engineering Education held in New York City, July 2–3, 1900. Vol. viii. Pp. xxviii + 377. (New York: Engineering News Publishing Company, 1900.) Price 2.50 dollars.

WHEN technical education is so much in the air, and so many consider that it is a cure for all our industrial troubles, it is interesting to see what another nation thinks of its own system of education. In America there exists a society for the promotion of engineering education, and we have the pleasure of reading their eighth volume of *Proceedings*—that of last year. The members of this association are those who are, or have been, engaged in responsible positions in the work of engineering instruction. There is a regular meeting for several days once every year, the whole of the papers which are read dealing with education as applied to industry.

The association seems to be most prosperous, both financially and in point of numbers; it is clear that meeting together of teachers is most useful to both teachers and students, and it is to be hoped that in this country a similar society may be formed, which would do much to educate public opinion as to what technical education exactly means. At present very few people understand what is wanted to be taught and whom to teach it to; an individual, even of the most impressive powers and personality, cannot speak with the same authority as a society which has only one end, namely, to improve our educational methods.

The presidential address of Prof. Ira D. Barker, dealing with the position of engineering education in the United States at the end of the century, is most instructive in showing what a strong hold technical instruction has on the other side of the Atlantic.

At the end of 1899 there were eighty-nine institutions offering full courses in engineering, in some cases seven different courses being open to students, the numbers attending full courses being 9679; of these colleges no less than 98 per cent. require the four years' course before graduation.

These schools must not in any way be considered as falling into the same category as our technical schools, which mainly address themselves to evening work for the artisan class. No doubt our technical schools do excellent work, but they in no way give that thorough and systematic instruction which is given in the American colleges, which do not wish to produce workmen, but to train successful leaders of industry. The trade school, which seems to have become inevitable in all countries under the stress of modern industrial competition, is evidently making its way in America, but, unlike us, no attempt is made to teach a boy a trade in his spare hours during the evening, but attendance is required during his entire time. The course really forms a part of the high school curriculum, and, while not developed to the same extent as in Germany, it is clear that Americans look to some such school to give that training which was in olden days given to the apprentice, but which will soon have become impossible to acquire in a modern works.

Perhaps the most interesting paper in the *Proceedings* is one by a committee on American industrial education. Great prominence is given to the manual training method, not only for kindergarten work, but for all grades of education up to the highest; as is there stated, the system is costly, but the results are said to be calculated to astonish those who have never seen the manual training system in operation.

The agricultural and mechanical colleges, founded in the first instance by land grant bills, are evidently the backbone of American education as regards applied science. Some colleges, such as Cornell, have developed in all directions, while others have confined their scope to purely practical subjects.

In all cases the instruction is based on a wide basis of those pure sciences which are the foundation of all technical knowledge. The Americans go further than we do, and give up a part of the course to purely literary subjects in order to give a broader education.

The correspondence technical schools are probably peculiar to America and are of quite a recent date; they are purely private concerns, which offer to give complete instruction by a course of papers. As the committee remark, the majority of students who commence soon drop the courses, but the convenience of learning by post is considered so great that these correspondence classes will probably become permanent.

The night school system is condemned by the committee in a most positive manner. The learner starts to learn after a heavy day's work, and after the classes are finished mind and body are alike exhausted.

No systematic course of study is possible owing to lack of time, while the whole atmosphere of the school is said to be very far from stimulating and encouraging. We are quite in agreement with this committee on this subject, and wish that people would not place so much reliance on the work of evening classes.

We conclude with an extract from some remarks made by Prof. Alderson, of Lafayette, Miss.:—

"Those who have had an opportunity to look into this matter probably know full well that to-day the industrial decadence of England is due to her failure to recognise the proper status of engineering education."

Such remarks are not pleasant reading, but often a dose of bitter truth is beneficial. Let us hope that it may not be too late for the warning to be of service.

F. W. Burstall.

OUR BOOK SHELF.

Chemical Technology; or, Chemistry in its Applications to Arts and Manufactures. Edited by C. E. Groves and W. Thorp. Vol. iii. *Gas Lighting.* By Charles Hunt. Pp. xviii + 312. (London: J. and A. Churchill, 1900.) Price 18*s*.

This, the third volume of a well-known work on chemical technology, gives a history of the manufacture of gas and its application to the purposes of illumination. After a short historical introduction, about three-quarters of the remainder of the book is occupied with a description of the mode of manufacture, purification and distribution of coal gas as carried out in this country. The consideration of gas burners then takes some fifty pages, the questions of the testing, analysis and determination of the heat of combustion of gas occupying about twenty pages. The apparatus used in the manufacture of coal gas is described in great detail, chapters being devoted to the construction and use of retorts, furnaces (several regenerative furnaces being described in this section), stoking machinery, condensers and scrubbers, purifiers, the measurement and storage of gas—the numerous forms of gasholders being very fully given—governors, distributing mains and pipes, and gas meters.

The mode of treatment throughout is that of an engineer, or rather a gas engineer, writing for gas engineers, and as representing the wide experience of the author in this respect the work will doubtless be found necessary on the bookshelves of every manager of a gasworks. The only criticism which may be offered in this respect is that the question of water-gas manufacture and distribution is not treated with the fulness which the growing importance of the subject deserves, a defect which may perhaps be attributed to the fact that it is only within the last year or two that public attention has been drawn to this subject by the agitation of certain public authorities against the use of this gas, and the subsequent appointment of a committee of the Board of Trade to consider the matter. From the absence of any mention of this, and from other indications, it is clear that the book was completed some two years before the date of publication. Thus the limits of sulphur impurity allowed in the metropolis are incorrectly stated, and no mention is made of the complete alteration in the method of testing London gas prescribed by the London Gas Referees in 1898.

But a more serious objection is the mode of treatment of the subject as a whole. As one of a series of chemical handbooks, it is natural to expect that the subject would be treated from a chemical, or at all events from a scientific, as opposed to an empirical, point of view, and this is by no means the case. The growth of gas manufacture in this country has been essentially empirical, and, although dealing with a chemical manufacture, has been developed almost exclusively by engineers without any special chemical knowledge. This is faithfully mirrored in the work under notice, in which mechanical details are given with minute accuracy, but chemical details are alluded to very briefly. Incidental references are made to the modes of analysing coal gas at various stages of its purification, although even here preference seems to be given in gasworks to rough and empirical apparatus. It is noteworthy that whilst the title of the book is "Gas Lighting," the question of photometry is altogether omitted; and although, as mentioned in the earlier chapters, the temperature at which the coal is distilled is of supreme importance as regards its quality and quantity, no mention is made of the use of any form of high temperature thermometer, nor, judging from the present work, does the pyrometer seem to be regarded as an essential part of the equipment of a gasworks.

There is still room for a work on coal gas which shall treat of the subject from a scientific as opposed to the empirical standpoint.

Elements of Quaternions. By Sir W. Hamilton. 2nd edition. Edited by C. J. Joly. Vol. ii. Pp. liv + 502. (London: Longmans and Co., 1901.) Price 21*s.* net.

THIS being the second volume of the reprint of a book that has become classical, and is known, by reputation at least, to all mathematicians, it is unnecessary to review it at much length. A comparison, however, seems to be called for between the work of the master and that published by his great disciple, Prof. Tait, since the first edition of the "Elements" made its appearance. The methods of treatment adopted differ radically. Prof. Tait's book is "essentially a working one," and for the most part contains only those formulæ that are necessary to a student when he commences the study of quaternions, and will afterwards be his working formulæ for general use. Sir W. Hamilton's book, on the other hand, aims at completeness. It gives fifty-three transformations for the vector of torsion of a curve in space, and treats the whole of the theory of curves and surfaces with the same elaboration! This wealth of methods and formulæ, which will only confuse the student who wishes to learn quaternions merely in order to apply it in his investigations in physics, &c., makes the book indispensable to the student who studies the subject for its own sake, or who wishes to deepen or consolidate the knowledge of it that he already possesses. Hamilton passes over statics and rigid dynamics quickly, but he treats dynamics and Fresnel's wave surface with his usual fulness.

About a quarter of this volume is occupied by notes by Prof. Joly. Among these are some on the invariants of linear vector functions, on the tri-linear function, and on the kinematical treatment of curves and surfaces. There is a long note on the operator ∇, a symbol which Hamilton does not use in the "Elements." These notes are very valuable, both because they bring the work up to date, and because they are very suggestive of fields for original investigation. We regret that mention is not made of the properties of the quaternion that is the sum of the vector and scalar potentials in the case of irrotational fluid motion, &c., and that several useful words, such as "curl," "convergence," "vector potential" are little used. No mention is made of the notation (f, g, h) for a vector.

A difficulty under which quaternions at present suffers is that, on the one hand, a worker in a branch of applied mathematics does not care to publish papers in quaternion notation for fear that few will understand him; and, on the other hand, that the lack of such papers discourages the study of quaternions. The notation just referred to seems likely to afford a convenient bridge between Cartesians and quaternions. An investigation of the electromagnetic wave surface by Prof. Tait is quoted in a footnote. It might have been added that the surface was first found by Heaviside. The omission is no doubt due to Heaviside's use of vector algebra, but it is perhaps allowable to consider the latter to be quaternions written in a modified (but not improved) notation. H. C. P.

Our Country's Shells and How to Know Them: a Guide to the British Mollusca. By W. J. Gordon. Illustrated by A. Lambert. Pp. vii + 152. Thirty-three coloured plates. (London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd.) Price 6*s.*

COLLECTORS of British shells will find this volume very useful for reference. The plates include coloured pictures of all our mollusca having shells, drawn life size in most cases, and also representatives of each genus without shells. Analytical tables are given to facilitate identification, and there are chapters on the habits and structures of the mollusca. If the collection of shells induces students to study the characteristics of the living animals, the book will be a means of education in natural history as well as a convenient reference manual.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Our Mountain Seclusion.

IN these days of continuous railway expansion it is only natural and desirable that our mountain solitudes should be made accessible to the general public. But obviously this praiseworthy object should not be attained by the destruction of the very seclusion which it is proposed to reach. A line of railway, with its cuttings, tunnels, embankments, stations, smoke and noise, will carry us much more swiftly and conveniently into a remote glen than the older and quieter modes of locomotion, but we then find that the charm of loneliness which used to give the glen its special fascination has disappeared. Where this transformation is absolutely necessary for the general benefit of the public we must submit to it, though with a sigh. But where the necessity or even the advantage may be disputed, surely the beauty or grandeur or solitude of untouched and unspoiled nature ought to be allowed to have a potent influence in the decision of such matters.

I have just heard of an assault at present being waged against the sanctities of Snowdon, and though it may be impracticable to ward off or mitigate that assault, and possibly too late, even if originally practicable, the attention of all lovers of scenery and of all geologists may well be drawn to it. A bill which has been introduced into Parliament for the construction of the Portmadoc, Beddgelert and South Snowdon Electric Railway, or Tramway, has passed the House of Lords and the Examiners in the House of Commons. If the line is ultimately sanctioned it will greatly lessen the quiet beauty of one of the loveliest and most secluded scenes in Britain—the easily accessible valley on the south side of Snowdon. I understand that, as the result of pressure, the Company has given way with reference to a proposed embankment in the Pass of Aberglaslyn, and will content itself with a brief disappearance in a tunnel. But geologists will learn with vexation that one important part of the scheme consists in the embanking of that picturesque mountain tarn, Llyn Llydaw, for the purpose of obtaining water-power. I need not refer to the special interest and importance of this lake-basin in questions of glacial and physiographical geology. Though it has long been studied, it has not yet yielded up all that it has to tell in these departments of science. But the transformation proposed to be effected by the company will silence it for ever by destroying the evidence which it can now afford.

Can nothing be yet done to save this geological sanctuary from the vandalism of the modern company promoter?

June 22. ARCH. GEIKIE.

The National Antarctic Expedition.

THERE is one allusion in the article on the above subject last week which calls for a few words from me. I refer to the first introduction of the word "civilian." Through the kindness of a friend I have recently had the opportunity of seeing a copy of the agenda. The agenda correspond with the minutes, and the word "civilian" is used in both. I had myself forwarded the motion concerning the scientific leadership to the secretary to be put on the agenda, and the word "civilian" certainly had no place in my communication.

At the meeting I moved, and Prof. Herdman seconded, the motion in the terms of my original communication, and neither of us noticed the change on the agenda paper.

We must therefore plead guilty to some carelessness and inattention; but the argument in my letter to the Fellows of the Royal Society is not seriously affected. An important change, exceeding the instructions drawn up for the guidance of the Executive Committee, is not, on any reasonable view, properly introduced by a single word which appears in the agenda and is not noticed or used by the mover and seconder of the motion. So important a question of principle obviously demanded very special discussion.

June 22. EDWARD B. POULTON.

Stress—Its Definition.

THE important word *stress*, denoting a fundamental conception in dynamics, is one as to the meaning of which no haziness or doubt ought to be permitted by the scientific community.

In your review of Prof. Gray's "Physics," the reviewer criticises the use made of the word in question, and makes the statement: "Strictly a stress is measured by the force applied per unit of area; it has the dimensions of force divided by the square of a length. . . ."

No authority is quoted to justify this statement. Does such authority exist? On collating the statements regarding the meaning to be attached to the word in some of the most authoritative works in the language, I have found a considerable want of agreement.

Going back to Rankine, who is credited with having introduced the word *stress* as a technical term into mechanics, we find the following paragraph in his paper "On Axes of Elasticity and Crystalline Forms" (1855):

"In this paper the word *Strain* will be used to denote the change of volume and figure constituting the deviation of a molecule of a solid from that condition which it preserves when free from the action of external forces; and the word *Stress* will be used to denote the force, or combination of forces, which such a molecule exerts in tending to recover its free condition, and which, for a state of equilibrium, is equal and opposite to the combination of external forces applied to it."

Again, in his "Applied Mechanics" (1860), we find, in § 86: "*Stress, its Nature and Intensity.*—The word STRESS has been adopted as a general term to comprehend various forces which are exerted between contiguous bodies, or parts of bodies, and which are distributed over the surface of contact of the masses between which they act. The INTENSITY of a stress is its amount in units of force, divided by the extent of the surface over which it acts, in units of area."

Then, in § 87, Rankine classifies three kinds of stress, (1) *Thrust or Pressure* (2) *Pull or Tension*, and (3) *Shear*, or *Tangential Stress.*

Further, in § 96: "*Internal Stress in General.*—If a body be conceived to be divided into two parts by an ideal plane traversing it in any direction, the force exerted between those two parts at the plane of division is an *internal stress.*"

Clerk Maxwell, in "Matter and Motion," Art. 37, says: "The mutual action between two portions of matter receives different names according to the aspect under which it is studied, and this aspect depends on the extent of the material system which forms the subject of our attention.

"If we take into account the whole phenomenon of the action between two portions of matter, we call it Stress. This stress, according to the mode in which it acts, may be described as Attraction, Repulsion, Tension, Pressure, Shearing Stress, Torsion, &c."

Again, in Art. 101.—"Stress.

"The next step in the science of force is that in which we pass from the consideration of a force as acting on a body, to that of its being one aspect of that mutual action between two bodies, which is called by Newton Action and Reaction, and which is now more briefly expressed by the single word Stress."

Thomson and Tait's "Natural Philosophy" (1867), Art. 658 (referring to the theory of elastic solids). ". . . the forces called into play through the interior of a solid when brought into a condition of strain. We adopt, from Rankine, the term *stress* to designate such forces, as distinguished from strain defined to express the merely geometrical idea of a change of volume or figure."

Thomson (Kelvin) in the 9th edition of the "Encyclopædia Britannica," article "Elasticity": Mathematical Theory, Chap. i. "Def. A stress is an equilibrating application of force to a body."

Tait, in "Newton's Laws of Motion" (1899), Art. 45:

"A pair of equal and oppositely directed forces, acting in one line, is a particular case of what is now called a *Stress.* The stress along a stiff rod (necessarily the same across every transverse section) may be either a *Thrust* or a *Tension*, that along a string or chain can be a *Tension* only. [But the term stress, in its widest signification, means *any* system of equilibrating forces.]"

"In a fluid the stress at any point is generally what is called *Hydrostatic Pressure*, whose characteristic is that the stress is the same across a small given plane area. . . . In all these cases the stress is measured by the amount per unit area of the surface on which it is exerted."

Love, in "Theoretical Mechanics" (1897), Art. 122, defines the stress at a point A across a plane interface passing through A, as the force per unit area exerted across a small area whose centroid is A.

From the preceding quotations there would seem to be a double ambiguity in the present usage of the word *stress.*

Firstly, it may be used to denote the whole mutual action between two portions of matter, A and B, say, in which case it would be specified by stating the force or system of forces exerted either by A upon B, or by B upon A; or it may be used to denote the *force per unit area* exerted by A upon B. The latter is clearly less widely applicable (torsional stress, *e.g.*, cannot be reckoned per unit area), and corresponds to what Rankine calls *intensity of stress*, or what is by some teachers appropriately named *unital stress.*

Secondly, the term *stress* may be defined as in the "Elasticity" article in the Encyclopædia to be an "equilibrating application of forces," or, as by Maxwell, to be the complete phenomenon including the "Action and Reaction" of Newton's Third Law of Motion.

To my mind there can be no doubt as to the greater usefulness of the latter definition, even though the former may be more consistent with some of Rankine's statements on the subject. It will be noted that in my quotation from Prof. Tait's work there seems to be a vacillation between the two meanings (what is meant there by "stress across a transverse section," or "stress across a small plane area"?), though he explicitly adopts the former alternative; and in the paragraphs of "Thomson and Tait" immediately following that quoted above there seems to be a similar shifting of ground in applying the term, while Maxwell's use of the word is consistent with his clear definition. This in itself argues strongly for the Maxwellian use of the word. Besides, the "equilibrating application" definition would seem to leave us in the lurch when we wish to name the internal forces of bodies not in equilibrium. And all who have had much experience in teaching dynamics to beginners must appreciate the help which the word in its Maxwellian sense affords in getting the student to see the difference between reaction and equilibrant, and to stop asking one such conundrums as "If action and reaction are equal, why does a body move?" And of course it is precisely the beginner for whose benefit we should take the trouble to be consistent in the use of words.

Let me conclude by offering the following suggestions for what they are worth:—

(1) Let the word "stress" be defined and used as in Maxwell's "Matter and Motion."

(2) Let "unital stress" or "unital stress at a point across a plane" be used as defined in §122 of Love's "Theoretical Mechanics." R. F. MUIRHEAD.

Glasgow, June 4.

I HAVE to thank the Editor for his courtesy in allowing me to see Mr. Muirhead's interesting letter. I quite agree that the meaning attached to the word "stress" by eminent writers during the fifty years from the time of Rankine to the present day has varied. At the same time, I observe that the only two definitions of the "measure of stress" which are quoted are of recent date, and both state clearly that a stress is measured by the force per unit area, though I find this same definition in Thomson and Tait, 1867 edition, Art. 661, a few lines below the quotation given by Mr. Muirhead. I think, then, I may claim sufficient authority for my statement, "Strictly a stress is measured by the force applied per unit of area," and for the doubt which I expressed as to the desirability of introducing the word "stress" as practically synonymous with "force" in a discussion of Newton's second law of motion.

While I share Mr. Muirhead's regret at the limitation thus imposed on the meaning of a general term "stress" as indicating the mutual action between two bodies, I hardly think his suggestion to distinguish between "stress" and "unital stress" will meet the case. REVIEWER.

Hybrid Oochromy, with a Note on Xenia.

IN a note on "Telegony, Xenia and Hybrid Oology,"[1] which appeared in *Natural Science* (vol. xiv. p. 394, 1899), I introduced the last-mentioned term to denote a singular phenomenon

[1] At the request of the editor I have altered the term hybrid oology to hybrid *oochromy*, which I agree is in many ways better, except that it would seem to refer to the coloration of the egg to the exclusion of its microscopic structure.

said to have been observed in birds, viz., that when a hen is fertilised by a cock of another kind the resulting egg is contained in a shell tinted, more or less, like those laid by the cock's own breed. At the time, I must confess, I was rather inclined to doubt if it did really occur, or if it were not a simple reversion, or a mistake, when my attention was drawn still closer to the subject by a friend who had kindly offered to assist in obtaining, if it were possible, additional proofs of telegony by first crossing a canary hen with a greenfinch cock and then returning her to her own breed. This was done, and resulted in three eggs being laid to the greenfinch. Their shells were all tinted more like the eggshells of a greenfinch than those of a canary. Two of these eggs were afterwards found to be infertile. This showed that the alteration in the tint of the eggshell had nothing to do with the nature of the fertilising spermatozoon. But the occurrence of hybrid oochromy could not be said to have been proved, for there is very little difference in the tinting of the eggshells of a canary and greenfinch, and I do not know whether the canary was purely bred or not.

I was thus anxious to find out for certain whether or not such an occurrence was possible. I therefore obtained three black Minorca hens, which had come of stock that had been purely bred for the last twenty years. The Minorca breed is the oldest variety of the famous Spanish fowls, of which the origin seems older than the recollection of it ![1] These three Minorca hens I penned up alone for more than four weeks, during which time thirty-two eggs were laid, and the shells of all of the later ones were of a very pure white colour.

The reason I had kept them alone for so long a time was that I required eggs entirely free from the intervention of any cock, and the commonly accepted opinion of poultry fanciers seemed to be that a period of nearly three weeks was necessary for the complete extermination of spermatozoa. However, to prevent any mistake, at the end of this time three eggs were artificially incubated for a period of forty-eight hours at the Durham College of Science, and they proved quite infertile.

After having thus demonstrated that the Minorca egg is contained in a pure white shell, I introduced into their pen a buff cock of the Cochin China breed, a breed famous for the brown with which its eggshells are tinted. The second egg laid after its arrival in the pen was provided with a shell of a very decided brown tint, and among a dozen or more laid within the succeeding two or three weeks, the shells of several were of a faint brown tint.[2] I was, however, unable to observe any difference in the microscopic structure of the eggs, such as is described by Herr von Nathusius. (See "Dictionary of Birds," by A. Newton, p. 190.)

This remarkable case appears to me to be an almost incontestable proof that hybrid oochromy does, at times, occur, as the only other way for accounting for pure bred black Minorca hens laying brown tinted eggs would be that they were reverting to some brown-egg-laying ancestors, a very unlikely supposition when we remember the age of the breed.

The next question to answer is—How does hybrid oochromy take place? I feel quite convinced, both from my own observations and those with the above-mentioned canary, that the tint of the eggshell is not, and cannot be, affected by the nature of the fertilising spermatozoon, and so we must turn our attention to the spermatic fluid, the chemical properties of which, acting in conjunction with those of the products of the shell-gland, will probably be found to be sufficient to cause this change of tint.

Hybrid oochromy has, in company with a closely associated phenomenon in another kingdom (I refer to Xenia), often been referred to as a case that cannot be explained by the Weismannian theory of heredity, *i.e.* the continuity of the germ-plasm. If the above explanation (and I can suggest no other) of hybrid oochromy should be proved to be correct, it is easily seen to be merely a chemical change and wholly apart from the phenomena of fertilisation. In the same way I should think it is very possible that xenia might be found to be not unconnected with the conjunction of the male and female elements forming the endosperm. It doubtless will be shown before long whether or not these two attempted explanations be correct. They will, I hope, however, tend to lessen the opposition to the Weismannian theory by showing how a fact which, at first sight, appears absolutely antagonistic thereto is found to be in complete accordance with it. It also shows what a deep effect may be induced in living organisms by the interaction of the chemical products of their glands.

I must here take the opportunity of expressing my best thanks to the Durham College of Science, Newcastle-on-Tyne, for allowing me the ground, &c., on which to conduct the experiment.

G. P. BULMAN.
Newcastle-on-Tyne.

[2] Since writing the above I have incubated two of these eggs and found them fertile. At first sight this would seem to contradict the explanation given, but although I hold that fertilisation is not necessary, it certainly may take place in some cases.

The Swimming Instinct.

I HAVE just tested the inherited powers of swimming in newly hatched pheasants. I find that when placed in tepid water, at the age of about thirty hours, they swim easily with well-co-ordinated leg-movements and show very little signs of distress.

C. LLOYD MORGAN.
University College, Bristol, June 24.

RECENT SCIENTIFIC WORK IN HOLLAND.

BEGINNING with that which is of most general importance, we draw attention to the recent work of Prof. Hugo de Vries, of Amsterdam. Prof. de Vries, who is well known as a botanist and biologist and whose name is familiar to those acquainted with the history of modern chemistry, has just published the first part of a book entitled "Die Mutationstheorie. Erster Band. Versuche und Beobachtungen über die Entstehung von Arten im Pflanzenreich" (Leipzig: Veit, 1901), containing, as the title indicates, the account of a series of observations on the formation of new species in plants. Starting from the fact, well known to florists, of the appearance of "single variations" in their flower-beds, de Vries has been trying to find wild flowers which would show the same phenomenon. Of the 100 species investigated only one appeared to possess the property which was looked for, the *Œnothera Lamarckiana*, originally from America, but at present growing wild in Holland. Now about ten years ago de Vries transferred specimens of this plant to the botanical gardens at Amsterdam, and up to date he has studied as many as 50,000 of its descendants.

Of these 50,000 about 49,200 were in no respect different from the original patriarchal *O. Lamarckiana*, showing no tendency towards gradual change in any special direction, but only the common small fluctuating "variations" as regards size and appearance on either side of a normal, in fact resembling in that respect other plants and animals which are left to themselves without being interfered with.

Quite otherwise the 800 other plants. None of these, although appearing spontaneously, could be said to be representatives of the species *Lamarckiana*, from which they were descended. De Vries arranges them in seven distinct species, viz. 1 of *O. gigas*, 56 of *O. albida*, 350 of *O. oblonga*, 32 of *O. rubrinervis*, 158 of *O. nanella*, 221 of *O. lata* and 8 of *O. scintillans*. Now comes the crucial question of the whole investigation. What right has de Vries to look upon the differences between these seven species and the original species as being of a different order from the variations between the specimens of each species, and what entitles him to call these differences *mutations* as opposed to variations? The answer is this: a representative of these new species produces descendants the majority of which unmistakably belong to the same species as itself. Not all the new species behave in the same way; as an instance, the only representative of *O. gigas* was isolated and made to fertilise itself. From it were obtained 450 plants, all of which, with only one exception, were *O. gigas*, the one exception not being a return to *Lamarckiana* but belonging to a new variety. The plant is a strong one and retains its properties in subsequent generations so far as investigated.

The *O. albida*, on the other hand, which appeared frequently, is a weak plant, not very fertile, but perfectly constant so far as it went.

The last species in the above list, the *Œnothera scintillans*, differs from the others in this respect, that it is extremely unstable, *i.e.* possesses the property of mutation to a high degree, a large proportion of its descendants belonging to other species, specially *O. oblonga* and *Lamarckiana* itself.

Want of space prevents us from going into further details. Enough has been said to show that de Vries has evidently made a momentous discovery. So far as his observations go, new species appear *suddenly* by *mutation*, never as the outcome of a progressive *variation*. With legitimate pride the author declares that he has been able for the first time to watch the formation and development of new species. The facts are so striking and convincing that an outsider like the reviewer cannot but feel that a new period in the theories of the origin of species and of evolution has been inaugurated.

As we saw, some of the new species which made their appearance did not seem to be inferior in stability to the mother-species; on the other hand, one of the species, the *O. lata*, only appeared as female plants without pollen, and the *O. albida* did not show the same vitality as the others and was evidently doomed to disappear again. The observations, therefore, do not support the idea that in the formation of new species Nature is carrying out a definite plan; on the contrary, it all looks like accident. A new species may be one strong and fertile enough to remain, and possibly, under favourable conditions, replace the mother-species, but it may just as well be a sickly kind without any chance in the struggle for existence. For the struggle for life between individuals de Vries substitutes the struggle for continued existence between species, the new species always appearing suddenly.

De Vries' views are thus directly opposed to the common form of the theory of evolution; not that the importance of the single variations had escaped attention altogether, but they were always lost sight of, and prime importance is generally attached to the selection through the ordinary variations. De Vries' experiments support the results arrived at by Scott and other palæontologists that there is no evidence in the successive strata of the earth of a gradual development of one species into another and that everything points at small but sudden transitions.

It can hardly be believed that the species which de Vries happened to come across can be the only living one possessing the property of mutation, and men of science may therefore look forward to a new period of extensive research on the lines of de Vries' work. One feels that new life has been infused into the problem, and that tangible facts are now available and experiments which will replace a good deal of rather empty theorising and hollow controversy between rival speculations.

Turning to physical research we naturally think, first of all, of the discovery made by Prof. Zeeman some years ago when still assistant at Leyden in Prof. Onnes' laboratory. This discovery of the influence of a magnetic field on the period and character of light radiated by a source in the field came just at the right time to bring the theory of ions or electrons into prominence, a theory the necessity of which had already appeared in many ways, and which had been worked out for the first time by H. A. Lorentz. In fact, without any calculation it is easily seen what influence a magnetic field must have on the light-vibrations, if these consist in the vibrations of charged particles. We have only to resolve the vibration of the electron in the direction of the field and at right-angles to it, and, again, the latter component into two circular vibrations of opposite directions, to see at once that the magnetic force must increase the centripetal acceleration in the one and diminish it in the other circle without affecting the third vibration; thus the ordinary doublet in the direction of the field, and the triplet in a direction at right-angles to it, both with their proper states of polarisation, may be directly inferred from the theory in its simplest form. The direction of the circular polarisation of the doublet shows the preponderance of the negative over the positive electrons in producing the phenomenon, and from the magnitude of the change in wave-length, *i.e.* the width of the doublet, the ratio of the charge of the electrons to their mass can be inferred.

It need not be here explained how these conclusions were confirmed by, and confirmed results obtained in the study of the conduction of electricity in gases, by J. J. Thomson and his pupils and others. Zeeman's phenomenon soon became public property, and has since been developed by many others as well as by Zeeman himself.

H. A. Lorentz, whose name is connected with Zeeman's discovery and its immediate explanation, published the first complete account of his electron-theory in 1892 in French, and a more complete version in 1895 in German ("Versuch einer Theorie der electrischen und optischen Erscheinungen in bewegten Körpern." Leyden: Brill). To this theory Lorentz was led by his discussion of aberration phenomena; there is, perhaps, no phenomenon which is so readily explained in elementary text-books but gives so much trouble when properly discussed as aberration.

Lorentz's researches led him to adopt Fresnel's theory, which assumes that the ether is at rest and that bodies move through it without disturbing it. This theory is in accordance with the negative results of Lodge's well-known attempts to put the ether in motion by spinning two heavy wheels close together in the same direction. Starting from this hypothesis and assuming that all electric phenomena—including light—in bodies are due to the presence, motion and vibration of electrons acting on each other through the ether, Lorentz developed a theory which leads to the proper Maxwell-equations for bodies at rest, and, moreover, explains the great majority of the experiments and phenomena relating to moving bodies—such as aberration, Doppler's principle and Fresnel's law for the velocity with which light is "dragged along" by a moving body through which it passes.

In order to account for the negative result of Michelson's aberration-experiment, Lorentz assumes, as was done independently by Fitzgerald, that a body moving through the ether diminishes in dimension in the direction in which it moves.

Particular interest attaches to a further development of the theory in the direction of an explanation of gravitation on electro-magnetic principles. In a paper published in 1900 Lorentz shows, first of all, that gravitation cannot be explained by assuming that bodies are constantly emitting electro-magnetic radiations of very short wave-length and high penetrating power, and that gravitation is due to the action of the ether in this disturbed condition on the electrons contained in bodies. Lorentz therefore proposes a different theory which is, in a way, an adaptation of Mosotti's theory of gravitation. Assuming that all bodies contain an equal number of positive and negative ions, it is clear that an explanation of gravitation by the mutual action of these ions, this action being, of course, transmitted by the ether with the velocity of light, can only succeed if it is assumed that in some way the condition of the field produced by a positive ion differs from that which is due to a negative ion; the action of the fields of the two kinds of ions on other ions is then supposed to be different, but in such a way that the action of a + field on a + or − ion is the same as that of a − field on a − or + ion respectively. Hence it follows that there will be no *electrical* action between two bodies containing ions, *i.e.* no tendency to separate the positive and negative ions, but a resultant action which constitutes what is observed as gravitation.

Lorentz then goes on to show the effect of the motion of attracting bodies in modifying the ordinary law of gravitation, and here he arrives at a remarkable result. The deviations from Newton's law depend on the ratios of the velocities of the bodies to the velocity of light, but only on the second power of these small ratios. Hereby he removes the grave difficulty first pointed out by Laplace against the assumption of a propagation of gravitation with a finite velocity, unless this velocity was millions of times greater than the velocity of light. By the peculiar way in which the condition of the ether is disturbed by a moving ion the effect of the motion on the apparent attraction is of a higher order of smallness, and, in fact, so small that no arguments can be drawn from astronomical data in their present degree of accuracy against the assumption. The latter result is independent of the special form which Lorentz gives to this theory, but holds for any electro-dynamical theory of gravitation on similar lines. Thus it looks as if there were no objection to applying this important unification to our physical theories. How Lorentz's work, some of it well known to every student of physics, is appreciated outside the narrow limits of his own country was shown not so many years ago when he received a call to the University of Munich to be Boltzmann's successor, an offer which he did not accept; and again in the end of last year, when physicists of all countries united in honouring him on his semi-jubilee as a doctor of physics. The *livre jubilaire* presented to him on that occasion contains some sixty contributions, about twenty of which are due to Dutch physicists, several to Lorentz's own pupils.

Not in the work of his pupils only do we trace Lorentz's hand; much of the work done by the Dutch physico-chemical school has been to a certain extent dependent upon his collaboration. In the book just mentioned we find this authoritatively declared by Bakhuis Roozeboom, the creator, we may say, of a new branch of physical chemistry, viz. the application of the phase-doctrine to all kinds of equilibrium. As one of the latest applications of this theory, we mention the attempted, and already partly successful, disentanglement of the iron-steel problem by le Chatelier, Roberts-Austen, von Jüptner, and Roozeboom himself (*Zeitschrift für physik. Chemie*). This application is instructive in showing how purely theoretical investigations may suddenly begin to bear upon highly practical problems and be applied for industrial purposes.

Roozeboom's pioneer work was carried out when still in the laboratory of the Leyden University. He is now at Amsterdam as van 't Hoff's successor. In his laboratory we find, working on independent lines, one of van 't Hoff's pupils, Dr. E. Cohen. Of the many investigations carried out by Dr. Cohen none is of more general interest than that on the enantiotropy of tin, partly carried out in conjunction with Dr. van Eyk. Tin—the white metal as we use it—has been known frequently, under the influence of intense cold, to change its condition completely by turning into a grey modification of lower specific gravity. This fact was known to the ancients, and the literature on the subject which the authors took the trouble to bring together forms quite a bulky collection. Nobody had succeeded so far in clearing up the chaos which surrounded the phenomenon and its explanation; this has now been done in the papers referred to. It appears that the change from white into grey tin is a reversible phenomenon, the transition temperature being 20° C.; this point was determined both with the dilatometer and electrically by the modern method of transition-cells. The transformation of white into grey tin goes on with increasing velocity the lower the temperature down to −50° C., after which it decreases rapidly. The existence of a maximum in the rate of transformation is in accordance with what occurs in the transformation of solids and liquids, *e.g.* the solidification of an undercooled liquid (Tammann). The velocity is increased (1) by the addition of a little grey tin at the beginning; (2) by the addition of pink-salt; (3) by exposing the tin to the low temperature for a long period, or by alternately cooling and warming it. Above 20° the grey tin is transformed into the white modification with very rapidly increasing speed the higher the temperature. Measurements have been made up to 40°.

From the above experiments it appears that the whole of our tin-world, except on a few exceptionally warm days, is in an unstable condition. Dr. Cohen is now trying to establish the existence of similar transition-points for other metals.

Van Bemmelen's recent work on absorption and the properties of jellies is looked upon both by chemists and by physiologists as fundamental. In his researches on jellies he has struck out a new line in making accurate determinations of the relation between the vapour pressure of the jelly and its composition. One of the several new points discovered in that manner is that jellies, when taken through cyclic transformation, show hysteresis-phenomena, a circumstance which would not occur if the equilibrium between the jelly substance and the water was of a purely thermodynamical character, in which case the phase-rule with its consequences would hold. The equilibrium in the jelly depends upon its history, which is in accordance with the hypothesis that capillary forces are at work. Van Bemmelen looks upon a jelly as a system of two phases—a solid mixture of the colloid and water, and, embedded in the interstices of this mixture, water. In some jellies this solid part shows remarkable sudden transformation into a modification of different composition, but there is no indication of the existence of hydrates. It will interest the reader to hear that Prof. Bemmelen, having recently reached the age of seventy, has become a "professor emeritus" of the Leyden University. In the light of his recent experimental work there is some humour in the Dutch law considering a man of seventy unfit for a professorship. Van Bemmelen is succeeded by Schreinemakers, who may be described as Roozeboom's *alter-ego* (I am speaking from a scientific point of view).

Each country has its own bread, its own type of boots, its own characteristic music—can the same be said with regard to contemporary science? Looking broadly at the nature of the scientific work which is undertaken in different countries, and the manner in which the work is carried out and put before the public, we observe differences which are the natural manifestations of national characteristics. At the same time, these differences are chiefly external, superficial. No science, not even any special branch of a science, is now the property of any one nation. What appears to direct the exertions of the men of science of a country along particular lines more than national character is the influence of the few eminent men which the country is fortunate enough to possess. This influence in a small country like Holland is obvious even to the casual observer.

The origin of the young Dutch school of chemists is no doubt to be traced to van 't Hoff. In the same way we might speak of a Dutch school of which van der Waals is the origin. Those who want to acquaint themselves with the work done recently in this branch of physics are referred to the new edition of van der Waals' book on the continuity of the liquid and gaseous conditions. (German. Leipzig: J. A. Barth, 1900.) It is unnecessary to say anything of the first volume, which is a reprint of the former edition, and a translation of which has been available for several years. The second volume which has been added to the book contains van der Waals' theories of mixtures of two substances in the liquid and gaseous conditions. First of all we find a reprint of van der Waals's paper of 1890 in the *Archives Néerland-*

aires and the *Zeitschrift für physikalische Chemie*, and, secondly, later developments and additions and the application to recent experimental work, most of which was carried out by Prof. Kamerlingh Onnes and his pupils at Leyden. Van der Waals pays an eloquent tribute to Prof. Onnes' merits in this direction in the dedication of this second volume. It appears that but for him the original theory might never have been published and would certainly not have borne any fruit.

The importance of a theory of mixtures, as of other theories, lies in this, that it may show the connection between a number of phenomena which otherwise have to be treated separately, and may, directly or indirectly, bring to light new ones. That a theory was urgently wanted in the phenomena of mixtures even of two substances need not be set forth. In a theory of mixtures we may distinguish different parts, more or less independent of each other, which together form the whole. It consists firstly of an application of thermodynamics to find out the rules for the coexistence of phases—the gas and the one or two liquids. To do this it is only necessary to assume the experimental fact that the properties of mixtures form a continuous series between those of the components and, therefore, that a mixture has an equation of condition of the same general features as that of a single substance. Van der Waals is not the only man of science who has been working on these lines, although doubtlessly the first who conceived the notion of such a theory. Not only had special problems relating to mixtures been successfully treated by Konowaloff and others, but Duhem, applying his method of the thermodynamic potential, had been working in the same direction. In the reviewer's opinion, however, it cannot well be denied that the method used by van der Waals in attacking the problem by means of the "free energy" ψ, and its graphical representation, is by far the most effective and the safest guide amidst the intricacies of the problem.

Leaving alone questions of priority, we may say that the theory as sketched has led, more or less directly, to the complete disentanglement of the critical phenomena of mixtures, to the tracing of the proper features of the various diagrams between the pressure, volume, temperature and composition, and to the discovery of various other new facts, such as the existence of maxima and minima in the critical temperature and their connection with minima and maxima in the vapour pressure, and the influence of pressure on the coexistence of two liquids. All these and many other points are fully set forth by van der Waals in this second volume.

Van der Waals has not, however, contented himself with that; from molecular considerations he was able to deduce an equation of condition for mixtures of a definite form, depending, as does his well-known formula for single substances, on attraction-constants a and volume-constants b. It is somewhat to be regretted that in the original paper no attempt was made to guide the reader in ascertaining in how far special results arrived at were dependent upon this special equation or not; everybody will feel the importance of the distinction, and certain controversies which have arisen in connection with the theory would have been prevented by a clearer distinction on this head.

The importance of this point has increased lately in connection with the modern conception of normal (non-associating) and abnormal (associating) substances. Van der Waals' equation can be used for normal substances as an approximate guide, although even for these the approximation is very rough and hardly amounts to more than a certain resemblance, at least at small and medium volumes. For abnormal liquids the equation cannot even profess to do that, and van der Waals' results, in so far as they depend upon this equation, are not applicable to these substances at all. Lehfeldt has noticed that, so far as we know, normal liquids mix in all proportions and that partial miscibility occurs when at least one of the components is abnormal. Van der Waals' theory does not confirm this, inasmuch as such values may be assigned to the constants in his equation as will lead to partial miscibility. At the same time, as no normal liquids of partial miscibility have been discovered so far, this subject is outside the scope of van der Waals' equation.

The reader must not get the impression that results deduced for normal liquids by means of van der Waals' equation are of small value owing to the inaccuracy of the equation. An instance will illustrate this. Van der Waals discusses the question, also treated by Ostwald and others, what function of the composition of a mixture its vapour-pressure is. He arrives at certain conclusions, one of which is that there cannot be more than one maximum or minimum, at least that the combination of a maximum and a minimum is very unlikely. Guided by this result, Hartman (Leyden) has discovered that there is an obvious error in Konowaloff's result for propionic acid and water, the curve for this combination being in contradiction to Konowaloff's own measurements, and Kohnstamm, working in van der Waals' laboratory, similarly discovered an error in Linebarger's result for benzene and carbon tetrachloride, a result which, if it had been confirmed, would have been even more striking, as both these substances are normal. On the other hand, Caubet and Duhem maintain to have realised the double phenomenon in question with methyl chloride and sulphur dioxide; if the latter result were confirmed it would certainly show in a striking way with what extreme caution conclusions drawn from the approximate theory have to be accepted.

Owing to the recent establishment of a "van der Waals fund," the famous author is now in a position to conduct experimental researches in his own laboratory. Several valuable memoirs have already appeared under this trust.

A very interesting departure has been lately made by Kamerlingh Onnes and his pupils to construct plaster models of the ψ surface entirely based on experimental data. Models of that kind will no doubt become a powerful assistance in the understanding of the intricate phenomena displayed by mixtures.

Turning our attention towards the work which is being done in the Leyden laboratory, we notice researches which are being carried on relating to Hall's phenomenon, the magnetic rotation of the plane of polarisation and many others. A special feature of the work is the constant use of low temperatures down to the boiling point of air. We feel at a loss what particular part of the work to review specially; in the small space available no justice could be done to any one without being unjust to others, and we abstain from reviewing anything in particular, considering that the "Communications from the Physical Laboratory at Leiden" are widely distributed and will, no doubt, be sent to anybody interested who takes the trouble to apply for them.

Much else might have been mentioned in this review, but we have tried to select that which would find the largest number of interested readers. J. P. K.

MAXIME CORNU.

THE hand of death has been heavy on the French botanical world. In recent years it has fallen successively on Duchartre, Baillon, Naudin, de Vilmorin and Franchet: all men in the foremost rank, whom their fellow-workers in England counted as sympathetic friends. And now the untimely and unexpected death of Maxime Cornu has come upon many of us—and not least at Kew—as a personal grief. I saw him last autumn in Paris full of the business of congresses into which he was throwing himself with irrepressible vivacity and energy. He had often complained of ill health. But nothing in his appearance had ever suggested to me ground for serious anxiety. I had hoped to have induced him to pay us a visit this year. I could not go to his funeral; nothing remains but the sad satisfaction of writing these lines to his memory.

Cornu was born July 16, 1843, at Orléans. The ability which he displayed in his schooldays seemed at first likely to be absorbed by studies on the literary side. But under the influence of his father and of his distinguished brother, Alfred Cornu, he devoted himself to mathematics, and with considerable success. He published in the *Nouvelles Annales de Mathématiques* papers on geometrical subjects. In my judgment there could be no better preparation for a scientific career. Mathematics, as they are taught in France, habituate the mind to the grasp of general ideas and accustom it to rise from isolated facts to large generalisations. The descriptive side of science, it cannot be doubted, has a cramping influence, and it is the fate of too many of those who devote themselves to it to be unable "to see the wood for the trees." Cornu's mathematical studies, at any rate, decided him for a scientific career, and at the "École normale supérieure" he eventually fixed on botany. He was for a time assistant to Duchartre, professor at the Sorbonne, a man remarkable in many ways, but possessing in a more than ordinary degree the power of presenting with French lucidity the results of current research, not forgetting those of English workers. While with Duchartre, Cornu produced in 1873, as his doctoral thesis, his well-known memoir on the Saprolegniaceæ, to which the Academie des Sciences awarded the Desmazières prize. From the Sorbonne he moved to the Muséum as aide-naturaliste to Brongniart, whose daughter he afterwards married. Brongniart brought down to our own day the best traditions of that illustrious school of French botanists whose philosophic insight into the principles of plant morphology and taxonomy has probably never been rivalled, and certainly not surpassed.

Under Brongniart, Cornu devoted himself to mycology. He published in a comparatively brief period a profusion of papers, in which one is at a loss whether to admire most the untiring industry, the sagacity, or the wide range of his work. Everything pointed to his taking a foremost place in this branch of botany.

But no one can be a mycologist without being drawn into the study of plant diseases, in which fungi play so large a part. Vegetable pathology early attracted Cornu, and he did much excellent work in it. We owe to him the principle, now so familiar as to seem almost obvious, of preventive treatment by the careful destruction by burning of the *débris* of plants which may harbour resting-spores.

In 1868 a mysterious disease made its appearance amongst the vines in the South of France. Planchon, the professor of botany at Montpellier (who owed his early training to Kew), discovered the cause in an insect—*Phylloxera vastatrix*—introduced from the New World. The injury which this ultimately inflicted on the principal cultural industry of France has been compared, and probably with justice, to that of the most devastating of wars. That France has risen triumphant above this, as above so many other disasters, is but one example of the indomitable courage of its people. Cornu, from his official position and special qualifications, was necessarily at once absorbed in the task—hopeless as it seemed at first—of combating the scourge. For at least ten years, from 1872 onwards, he was occupied in little else. It is needless to enumerate the prominent position in various inquiries which he filled; the most important was that of "secrétaire de la commission académique du Phylloxera." His memoir on the whole subject published by the Academy has always seemed to me, for completeness and finish, a model of what such a research ought to be.

Cornu became the acknowledged authority on the subject of the Phylloxera. It had not been foreseen at first that the scourge, when once emancipated from its American home, might, and probably would, invade every wine-growing country. There were those who thought it impossible that it could cross the equator. The expectation was falsified and, in spite of all precautions, it made its appearance at the Cape. I advised the Cape Government to have recourse to Cornu, and his services were as generously given as, I know, they were warmly acknowledged.

In 1884 Cornu succeeded Decaisne as Professor of Culture at the Muséum—a position, if not so extensive in scope as that of the Director of Kew, scarcely less onerous. I had made Cornu's acquaintance some years before, and the circumstance of our similar official positions speedily brought us into closer intimacy. The position of an administrator under Government does not suit every temperament. The enthusiast must expect his ardour to be quenched with a good deal of official cold water. To Cornu, who had something of the engaging qualities of the *méridional*, this was hard to bear. My sympathy with him in his troubles, which were often not small, was certainly sincere, but I am afraid often seemed to him phlegmatic. In any case, the worries of administration pressed hardly on him and, notwithstanding the counsels of common friends, diverted him from the scientific work which we all expected of him, and which his really brilliant powers entitled us to expect.

At the moment that Cornu entered on his new duties, France had turned its attention anew to the field in which, in the past, it had done so much—colonial enterprise. Cornu's ambition—and it was a legitimate one—was to utilise the somewhat dormant resources of the Jardin des Plantes in the work, much on the lines of Kew. For my part it was more than a pleasure to give him all the assistance in my power. Agriculture is the great civilising agency. To reduce nomadic and predatory tribes to cultural pursuits is perhaps one of the most effective of missionary enterprises. Cornu threw himself into the work with little short of passion. What he accomplished, both for the French colonies and for the enrichment of the gardens of his own country, with resources more limited than we have at our disposal in England, is to me surprising. But, unhappily, at the moment when he had attained some measure of success his forces failed him, and he was not allowed to see his work fully crowned with accomplishment.

Cornu was the most loyal of Frenchmen. Had he been less so, he would not have sacrificed to the interests of France the career he might have devoted to science. I cannot but fear that while he lived the sacrifice he made was not fully appreciated. Many of us have wondered that a man who had done so much had never been admitted to the Institute. But that recognition could not have been long delayed, and this adds another regret to his untimely death.

W. T. THISELTON-DYER.

NOTES.

M. MAUPAS, of Algiers, has been elected a correspondant of the Section of Anatomy and Zoology of the Paris Academy of Sciences, in succession to the late M. Marion.

THE Harben medal of the Royal Institute of Public Health will be presented to Prof. Koch at a dinner to be held on July 24. Tickets may be obtained from the honorary secretary, Dr. W. A. Bond.

THE ethnographical collection of shamanistic implements, bead-work, musical instruments, &c., presented by Miss Owen to the Folklore Society, is on exhibition for a few days at the rooms of the Anthropological Society, 3 Hanover Square, W.

THE newly constituted "African Society," founded in memory of the late Miss Mary Kingsley, will hold its inaugural meeting at the United Service Institution, Whitehall, this afternoon, under the presidency of the Marquess of Ripon. This Society has been started with the object of studying the languages, laws and customs of the continent of Africa.

THE annual summer meeting of the Society of Public Analysts will be held at Cambridge on Friday, July 19.

PROF. RUDOLF VIRCHOW has been elected a knight, with the right to vote, of the Order Pour le Mérite for Sciences and Art.

AN official announcement has now been made in regard to the Rockefeller Institute for Medical Research, toward the establishment of which Mr. John D. Rockefeller has recently given 200,000 dollars. We learn from *Science* that the directors are Dr. William H. Welch, Baltimore, president; Dr. T. Mitchell Prudden, New York, vice-president; Dr. L. Emmett Holt, New York, secretary; Dr. C. A. Herter, New York, treasurer; Dr. Theobald Smith, Boston; Dr. Simon Flexner, Philadelphia; Dr. H. M. Biggs, New York. The purpose of the foundation, as the name implies, is to furnish facilities for original investigation, particularly in such problems in medicine and hygiene as have a practical bearing upon the prevention and treatment of disease. The sum of money mentioned above is not an endowment, but may be used for current expenses. The Institute will be situated in New York City. A building will not, however, be erected at present, but research will be conducted in existing laboratories under the auspices of the directors.

THE members of the Institution of Electrical Engineers who are participating in the visit to Germany have been heartily received at Berlin. On Monday they were entertained at dinner by the Berlin General Electric Company and by the firm of Siemens and Halske at the Berlin Fire Prevention Exhibition. Herr Geheimrath Rathenau, in welcoming the English guests, is reported by the *Times* to have said that electrical engineering, in which it would be admitted that Germany had made great progress, was "nothing else than the child of mechanical engineering, which Germans originally learned in England in the factories of London, Birmingham, Glasgow, &c." He thought they would admit that the English masters might well be proud of their German scholars.

IN the House of Commons on Monday Sir W. Hart Dyke asked the President of the Board of Agriculture if he intended to transfer the powers of his Board in respect of agricultural instruction to the Board of Education, he intended that the Board of Agriculture should undertake the organisation and coordination of such instruction throughout England and Wales. In reply, Mr. Hanbury said: "I am not prepared to transfer elsewhere any part of the existing duties of the Board of Agriculture, the functions of which, especially with regard to agricultural instruction, might, on the contrary, with advantage be enlarged. I am unable to state as yet in detail how this can be brought about, but I attach great importance to the necessity for extending the work already done by the Board in collating and publishing the results of experiments and the most recent discoveries bearing on agriculture, both in this country and abroad, and also to the advantage to be gained by friendly cooperation between the Board and county councils in devising the best methods of instruction and experiment."

THE movement to establish a Washington Memorial Institution for post-graduate study and research in Washington appears to have met with success. It originated in the Washington Academy of Sciences, and the organisation and scope have now been agreed upon. The primary aim is to facilitate the utilisation of the various scientific and other resources of the Government for purposes of research, thus cooperating with all universities, colleges and individuals in giving men and women the practical post-graduate training which cannot be obtained elsewhere in the United States and which is now available only to a limited degree in the city of Washington. An Act of Congress approving these principles was passed in March, and reads as follows:—"That facilities for study and research in the Government Departments, the Library of Congress, the National Museum, the Zoological Park, the Bureau of Ethnology, the Fish Commission, the Botanic Gardens, and similar institutions hereafter established shall be afforded to scientific investigators and to duly qualified individuals, students, and graduates of institutions of learning in the several States and Territories, as well as in the District of Columbia, under such rules and restrictions as the heads of the Departments and Bureaus may prescribe." The organisation is independent of Government control, and the management is vested in a board of fifteen trustees and an advisory committee composed chiefly of the heads of Government Departments. *Science* states that the new institution will attain substantially the objects desired by the advocates of a National University, without being subject to the objectionable features of a university sustained by the Government in competition with the existing universities.

THE Council of the Society of Arts have awarded the Society's silver medal to the following readers of papers during the session of 1900–1901:—Major Ronald Ross, F.R.S., for his paper on "Malaria and Mosquitoes;" Dr. W. Schlich, F.R.S., for "The Outlook for the World's Timber Supply;" Lieutenant A. T. Dawson, late R.N., for "Modern Artillery;" Mr. Fritz B. Behr, for "The Proposed High-Speed Electrical 'Monorail' between Liverpool and Manchester;" Mr. Percy R. Macquoid, for "Evolution of Form in English Silver Plate;" Prof. Raphael Meldola, F.R.S., for "The Synthesis of Indigo;" Sir Joshua Fitch, for "School Work in Relation to Business;" Mr. Marconi, for "Syntonic Wireless Telegraphy;" Mr. Henry John Tozer, for "The Growth and Trend of Indian Trade—a Forty Years' Survey;" Colonel Sir T. H. Holdich, K.C.I.E., for "The Greek Retreat from India;" Mr. J. D. Rees, for "Madras, the Southern Satrapy;" the Hon. Sir J. A. Cockburn, K.C.M.G., for "The Commonwealth of Australia;" Lieutenant Carlyon W. Bellairs, R.N., for "The Coal Problem: its Relations to the Empire;" Mr. William Burton, for "Recent Advances in Pottery Decoration;" and Mr. Hugh Stannus, for "Some Examples of Romanesque Architecture in North Italy."

AMATEUR photographers visiting London, and desiring to obtain pictures of interesting sights and objects, will find of service a leaflet prepared by Messrs. Sanders and Crowhurst and Mr. R. W. Paul. A list is given of suitable subjects, arranged in six groups, each group being sufficient for a day's work.

A MEETING of the Physical Society will be held on Friday, June 28, in the Wheatstone Laboratory, King's College, Strand, by invitation of Prof. Adams. Papers will be read on the effect of a high-frequency oscillatory field on electrical resistance, by Mr. S. A. F. White; and on the spectrum of cyanogen, by Mr. E. C. C. Baly and Dr. H. W. Syers.

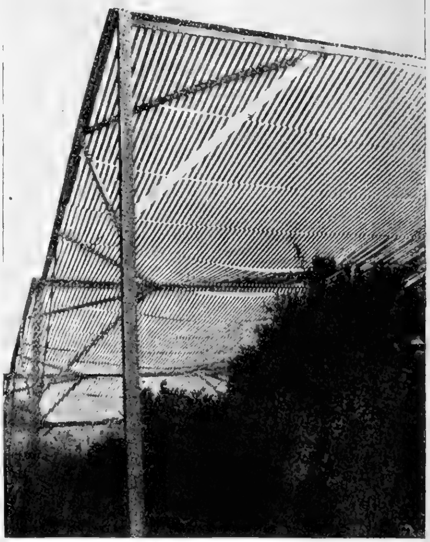
AN interesting incident is recorded in the *Engineer* (June 14). A petrol motor car returning from Biarritz to Paris came to a standstill near Etampes for want of petrol, and as another supply could not be obtained in the neighbourhood the driver resolved to try the only spirit obtainable—namely absinthe. He charged his car tanks accordingly, and afterwards declared that "the motor never ran better than with this improvised fuel."

PARTICULARS of the ethnographical survey undertaken by the Government of India in connection with the census, as suggested by the British Association, are given in the Allahabad *Pioneer Mail*. The following is a summary of the scheme prepared by the Government and sanctioned by the Secretary of State:—Local Governments will select from among their officers a superintendent of ethnography, who will undertake to carry on the inquiries proposed, in addition to his ordinary duties. The superintendent will correspond with the district officers with the object of ascertaining what persons in their districts are acquainted with the customs, traditions, &c., of particular tribes and castes. The information thus obtained will be collated by the superintendent, and will be supplemented by his own inquiries from such representative men as he can find, and by researches into the considerable mass of information in official reports, in the journals of learned societies and various books. The superintendent will work up all this material into a ystematic account of the tribes and castes of the province somewhat in the form adopted in "The Tribes and Castes of Bengal," and that followed by Mr. Crooke for the North-Western Provinces and Oudh. By working on these lines the Government of India believe it will be possible to get a fairly complete account of the ethnography of the larger provinces drawn up within four or five years. It is estimated that the survey will cost 10,000*l.*, excluding the cost of printing the results, which cannot be calculated at present. The Secretary of State has accorded his sanction to an expenditure not exceeding this amount. It is also proposed to collect physical measurements of selected castes and tribes. In Madras the work will be done by Mr. Thurston, superintendent, Central Museum, whose ethnographic researches in the south of India are well known, and who, it is understood, is likely to be selected by the Provincial Government as superintendent of ethnography for the Madras Presidency. The general direction of the scheme will be entrusted to Mr. Risley, whose official title will be for this purpose Director of Ethnography for India. The Governor-General in Council trusts that on this, as on former occasions, ethnologists and scientific societies in England and America will assist the Director with their advice, will refer to him points which they may wish to be made the subject of inquiry in India, and will, if possible, supply him with copies of publications bearing on the researches now about to be undertaken.

AMONG the many useful publications issued annually by the Royal Observatory of Belgium we draw special attention to "Éphémérides météorologiques et naturelles." The work is an excerpt from the "Annuaire météorologique" for 1901, and contains the monthly and annual values of the principal meteorological elements and phenological observations for Brussels (or Uccle) for each year from 1833 to 1900. Similar information relating to the wind has been published in a separate work. We extract the following interesting items from this long and valuable series of observations. The absolute maximum shade temperature was 95°·4 F. and the minimum 4°·4. The average annual rainfall amounts to 28·56 inches and the mean number of rainy days is 190. The relative humidity at noon is fairly uniform, varying in the yearly average from a minimum of 67·6 to a maximum of 79·9 per cent.

IN the *Bulletin* of the Cracow Academy M. S. Zaremba discusses the proof of the existence, for any given connected region bounded by a surface S, of a series of functions analogous to spherical functions and satisfying the well-known physical equation $(\nabla^2 + k^2)V = 0$. The fact that such functions exist was discovered by Poincaré, and demonstrated by Le Roy for surfaces satisfying certain conditions. Stekloff has studied the same problem from a different point of view, but the methods of Le Roy and Stekloff depend on certain transformations of the surface for which the existence of so-called fundamental functions has to be proved. M. Zaremba now claims, without employing any transformation, to have proved the existence of fundamental functions for any surface satisfying certain stated conditions, such as, for example, that the tangent plane at every point is unique. The series of functions has not been proved to be infinite in number, but this gap in the proof the author considers can be easily filled.

SYSTEMATIC efforts are made in California to reduce injury to fruits by frost. Mr. A. G. McAdie describes some of the means used in the U.S. *Monthly Weather Review* for February, and the accompanying illustration is one of several which illustrate his paper. This represents an elaborate structure of lath-screens in use upon one fruit ranch. The lath covering may be considered as forming a well-ventilated hot-house, and there is



Screen or protecting fruit from frost.

no question as to its protective value, but the expense of erecting it will prevent its wide adoption. An investigation of the conditions producing frost has shown that frost is primarily a problem in air drainage. Mr. McAdie states the principle that "wherever the air was stagnant the injury from frost was most marked; and conversely, wherever the air was in motion, there was little damage from frost." In California, much of the damage appears to be done by the sudden warming of the chilled fruit at sunrise. If a screen is interposed between the fruit and the sun, so that the warming is gradual, the fruit is saved from injury.

"SUNNY DAYS AT HASTINGS AND ST. LEONARDS" is the title of a well-illustrated and well-printed little handbook for south-east Sussex, by Messrs. W. H. Sanders and P. Row. There is a "six-inch" map of Hastings and St. Leonards, and another map, on the scale of an inch to four miles, of the country as far as Seaford, Tunbridge Wells and Ashford—all for the price of

6*d.*, being vol. xvi. of the handbooks published under the auspices of the "Homeland Association for the Encouragement of Touring in Great Britain and Ireland." Apart from the descriptions of places of historic interest, including many famous old castles, it is interesting to find chapters on the geology of the district and on the prehistoric people of Hastings, by Mr. W. J. Lewis Abbott. The great physical changes recorded in the rocks are briefly pictured, though with few local descriptions, and then Mr. Abbott (whose enthusiastic labours in this field are well known) tells of the works of man in Plateaulithic, Palæolithic and later ages, concerning which abundant material has been obtained in Sussex and other parts of the south-east of England. A good account is also given of the various objects of interest in the Hastings and St. Leonards Museum.

FROM the Report of the Australian Museum for 1899 we learn that Mr. A. J. North's "Catalogue of the Nests and Eggs of Birds found breeding in Australia" is making satisfactory progress. The work, which is to include thirty plates of eggs and forty of nests, will be expensive, so that its cost is to be spread over several years. Apart from a complaint as to lack of funds, the general progress of the Museum seems to be satisfactory.

TWO interesting papers on wild life in Australia appear in the May number of the *Victorian Naturalist*, the one, by Mr. D. le Souef, being entitled "Among the Waterfowl in Riverina," and the other, by Mr. C. French, "A Naturalist on the Mallee." In the latter reference is made to the appearance of a swarm of caterpillars of the "army worm," which caused incalculable damage to the "wallaby grass." The caterpillars were, however, attacked in turn by a fungus (*Entromophthora australis*), which probably made a clean sweep of the entire horde.

THE latest issue of the *Zeitschrift für wissenschaftliche Zoologie*, which completes vol. lxix., is mainly devoted to morphological subjects, although it includes a description of a new genus (Ludwigia) of holothurian from New Zealand, represented by a species described in 1897 as *Colochirus ocnoides*. The morphological subjects comprise the development of the rook, the nature of the reproductive organs of the Ctenophora, the development of the vertebral column of the rat, the structure of the gills of fishes, and the difference between the female reproductive organs in the gnats and mosquitoes of the genera Culex and Anopheles.

To the June number of the *Zoologist* Mr. W. W. Fowler communicates an interesting article on the winter singing of the thrush. Owing to the mildness of last November thrushes "were unusually numerous, and almost every individual seemed to be uttering some kind of song, and continuing it more or less from early morning, when the voicefulness was at its highest point, till sunset, and even later." The author set himself the task of determining whether this unusual outburst of song was due merely to the birds being in good condition, or whether it had any connection with the ensuing pairing-season. Despite a complete cessation between January 3 and 21, he inclines to think "that the great outbreak of song in the autumn was, in the case of mature birds at least, a forecast of the coming breeding-season."

THE most striking feature in the Report of the Field Columbian Museum at Chicago for the year 1899-1900 is formed by the full-page illustrations of groups of mammals mounted amid their natural surroundings. By far the best of these represents a party of five Somali hartebeests in the Haud desert, the attitudes of the animals being absolutely life-like. There is nothing to approach this grouping in our own national museum. The lectures delivered from time to time in the museum appear to attract good audiences. Two courses, one of eight and the other of nine lectures, were delivered during the period in question. They comprised anthropological, zoological and economic subjects. The total expenditure of the museum during the year was a little more than 24,000*l.*

WE have received a pamphlet indicating the contents of a bibliography and subject-index of the Schizomycetes (Bacteria) now appearing in the "Scientific Roll." It is stated to show the scope and extent of the work in January 1901, but is subject to alteration. The method of cataloguing seems to be to divide the subject into a number of groups—general, diseases, micro-organisms, &c.—each of which is again subdivided, and the subdivisions have appended to them the years in which papers on their subject-matter have appeared. In the second half of the work the matter is divided into years, and under each year an alphabetical list of authors is given, with the titles of their papers. The method of arrangement would have been rendered far clearer had a few specimen pages been included. The few references we have checked we have found to be accurately given. Judging from the list of contents there are overlappings and omissions. For example, "Bacillus of mouse typhoid" and "Bacillus typhi murium," "Bacillus of Plague" and "Bacillus pestis" are given as separate headings with different references, while "Micrococcus Melitensis" and "Bacillus pseudotuberculosis" seem to be omitted. The work may be, and might be made, a very valuable one, but details are wanting to enable a correct estimate as to its value being formed. For example, there is no indication whatever as to the journals, &c., that are to be indexed; a list of these should be given.

MR. BERNARD QUARITCH has issued a catalogue of the valuable entomological library collected by the late Mr. J. H. Leech, together with other important works on natural history and botany offered for sale at his establishment in Piccadilly.

MESSRS. DULAU AND CO. announce for publication in July a "Flora of Guernsey and the Lesser Channel Islands," by Mr. Ernest D. Marquand. The work will comprise classified lists, with full details of local distribution, of the flowering plants, ferns, fern-allies, characeæ, mosses, hepaticæ, fungi, lichens, sea-weeds, freshwater algæ, and diatomaceæ which have been found in Guernsey, Alderney, Sark, Herm, Jethou, Lithou, Crevichon and Burhou. Each island is treated as a separate and independent botanical area, possessing its own peculiar features. It is stated that upwards of 2500 different species are recorded for Guernsey alone.

THE syndics of the Cambridge University Press have undertaken the publication of the first part of the "Index Animalium," to the preparation of which Mr. C. Davies Sherborn has devoted so many years. The object of the index is to provide zoologists with a complete list of all generic and specific names given by authors to animals both recent and fossil since January 1, 1758, the date of the tenth edition of Linnæus' "Systema Naturæ." With each name will be given an exact date and a reference intelligible to the layman as well as to the specialist. The British Association appointed a special committee to watch over the inception and progress of the work, the preparation of which was undertaken in 1890. Financial support has been given by the British Association, the Royal Society and the Zoological Society, while the authorities of the British Museum have afforded continual assistance. The portion of the work already completed and in the press covers the period from 1758–1800 and consists of 61,600 entries.

WE have received from Messrs. Müller, Orme and Co. a specimen apparatus, designed by Mr. C. T. Tyrer, for use in making the Marsh-Berzelius test for arsenic. Commonly the flask in which the hydrogen or the arseniuretted hydrogen is generated is closed either with an ordinary cork or with an india-rubber stopper, and, with the object of arresting seleniuretted and sulphuretted hydrogen, the gas, as it passes from the flask to the mirror-tube, is brought in contact with lead acetate solution, sometimes bubbled through the liquid and sometimes passed through cotton-wool or over a roll of filter-paper saturated with the solution. Where cork has been in contact with arseniuretted hydrogen there is danger of sufficient of the arsenic compound being retained by this porous substance to render its continued use a possible source of error; with rubber there is always the chance that arsenic or antimony may be present as one of the constituents of the material, and as regards the use of lead acetate it has been urged that to bubble the gas through a small quantity of the solution is safer than to pass it through or over cotton-wool or filter-paper. The apparatus sent us has been designed to avoid the use of a cork or rubber stopper, and to include a convenient means of passing the gas through a minimum quantity of lead acetate solution. To a wide-necked flask of 200 c.c. capacity is fitted a hollow glass stopper, perforated by the gas-exit tube, which supports a bulb containing a small quantity of 10 per cent. acetate of lead solution. The stopper is ground to fit tightly into the neck of the flask, and as the gas passes up the exit-tube it bubbles through the lead acetate solution in the bulb and so on to a calcium chloride drying-tube, to which is attached the mirror-tube in which the arseniuretted hydrogen is decomposed. The apparatus is neat and effective.

THE additions to the Zoological Society's Gardens during the past week include three Derbian Wallabys (*Macropus derbianus*, ♂ ♀ and juv.) from Australia, presented by Captain Ben Jones; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. Thomas Mackenzie; an Egyptian Jerboa (*Dipus aegyptius*) from North Africa, presented by Mr. J. Manuel; an Active Amazon (*Chrysotis agilis*) from Jamaica, presented by Mrs. V. A. Taylor; a Darwin's Rhea (*Rhea darwini*) from Patagonia, presented by Mr. H. F. Fox; a Large-billed Weaver-Bird (*Ploceus megarhynchus*, ♂) from Naini Tal, deposited; a Baya Weaver-Bird (*Ploceus baya*, ♂), two Black-throated Weaver-Birds (*Ploceus atrigularis*), a Black-headed Finch (*Munia malacca*), a Chestnut-bellied Finch (*Munia rubro-nigra*), two Hybrid Finches (between *Munia malacca* and *M. rubro-nigra*) from India, presented by Mr. Frank Finn; two Bennett's Wallabys (*Macropus bennetti*) from Tasmania, a Black Wallaby (*Macropus ualabatus*) from New South Wales, a Ring-necked Parrakeet (*Palaeornis torquata*) from India, an August Amazon (*Chrysotis augusta*) from Dominica, fourteen Algerian Skinks (*Eumeces algeriensis*) from North-west Africa, a Derbian Sternothere (*Sternothaerus derbianus*) from West Africa, three Simony's Lizards (*Lacerta simonyi*) from the Canaries, eight Three-streaked Skinks (*Mabuia trivittata*), two Streaked Skinks (*Mabuia vittata*), a Hissing Sand Snake (*Psammophis sibilans*) from Syria, four Grey Monitors (*Varanus griseus*), five Common Skinks (*Scincus officinalis*), four Ocellated Sand Skinks (*Chalcides ocellatus*), six Turkish Geckos (*Hemidactylus mabouia*) from Western Asia, deposited; an Axis Deer (*Cervus axis*, ♂) from India, purchased; six Silver Pheasants (*Euplocamus nycthemerus*), four Gold Pheasants (*Thaumalea picta*), six Common Pheasants (*Phasianus colchicus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JULY.

July 1. 9h. Jupiter in conjunction with moon. Jupiter 3° 42′ S.
1. 19h. Saturn in conjunction with moon. Saturn 3° 36′ S.
2. 9h. 29m. to 9h. 47m. Moon occults B.A.C. 6710 (mag. 6·0).
3. 11h. 2m. to 14h. 6m. Transit of Jupiter's Sat. III.
5. 9h. Saturn in opposition to the sun.
15. Venus. Illuminated portion of disc = 0·936, of Mars = 0·900.
17. 10h. 34m. Minimum of Algol (β Persei).
22. 10h. 59m. Moon in conjunction with α Virginis (Spica).
24. Saturn. Outer minor axis of outer ring = 18″·08.
28. 9h. 51m. to 11h. 6m. Moon occults 21 Sagittarii (mag. 4·9).
28. 11h. Jupiter in conjunction with moon. Jupiter 3° 37′ S.
29. 0h. Saturn in conjunction with moon. Saturn 3° 34′ S.
29. 8h. 33m. to 9h. 48m. Moon occults *d* Sagittarii (mag. 4·9).

BLACK SPOT ON JUPITER.—On June 2, Sig. J. Comas Sola, working at the observatory of Barcelona with a six-inch Grubb equatorial (power 200), noticed a strange marking on System II. of the planet's belts. From the time at which it passed the central meridian on that day its longitude would appear to be about $\lambda = 73°·1$; its latitude would be about 15°.

The tone of the spot is almost black, with a light garnet tinge, and might without close attention be mistaken for the shadow of a satellite. It is very sharp and circular, but on careful examination a very pale penumbra is seen before and behind the spot itself, the posterior penumbra being the more prominent of the two.

No signs of this spot were apparent on May 31.

TEN-YEAR GREENWICH STAR CATALOGUE FOR 1890.—The second ten-year star catalogue recently issued from the Royal Observatory forms Appendix II. to the *Greenwich Observations* for 1898, and contains the reduced places of 6892 stars for the epoch 1890·0, from observations made with the transit circle during the period 1887–1896.

The various corrections investigated are described at length, one interesting point brought out being that the observations from 1895–1899 show a diurnal change in the position of the nadir, the observations taken about noon and midnight giving positive corrections to the observations made near the time of sunset.

Comparisons are also given with the data of other standard catalogues, from some of which the proper motions of 174 stars are deduced.

NEW NEBULÆ.—In the *Comptes rendus* (vol. cxxxii. pp. 1465–1467) M. Bigourdan gives a descriptive table of twenty-one new nebulæ discovered with the north-west equatorial of the Paris Observatory, bringing up the number found in this way to 392.

PARALLAX OF μ CASSIOPEIÆ.—The eighteenth volume of "Contributions from the Observatory of Columbia University" contains an investigation of the parallax of μ Cassiopeia, made by Mr. G. N. Baur from the Rutherfurd photographic measures of twenty-eight plates of the region taken during 1870–1873.

The final value determined for the parallax is

$$\pi = 0''·238 \pm 0·014.$$

A table is also included showing the positions of fifty-six of the neighbouring stars used in the determination.

NEGATIVE AFTER-IMAGES AND COLOUR-VISION.

FOUR years ago I described an apparatus by which apparent transformations of colour could be produced (*Proc. Roy. Soc.*, vol. lxi. p. 268; NATURE, vol. lvi. p. 128). The essential part of it is a disc, partly black and partly white, having an open sector at the junction of the black and white portions, as shown in Fig. 1. If such a disc is caused to turn five or six times in a second while its surface is strongly illuminated, a coloured object placed behind it and viewed intermittently through the opening generally appears to assume an entirely different hue, more or less approximately complementary to the true colour of the object. A piece of red ribbon, for example, is seen as bluish-green and a green one as pink. The effect is due to the formation of negative after-images upon the white portion of the disc.

A number of observations made with this apparatus showed that the "pulsative after-images," as they may be called, differed in several important respects from the ordinary negative after-images seen upon a white ground after the gaze has been fixed for some time upon a coloured object. Among other things, they often appeared much more intense or saturated, which for obvious reasons was rather surprising. And again, it was found that the colours of the pulsative and of the ordinary after-images were sometimes very different. The pulsative after-images of red, of purple and of orange, for instance, were all of nearly the same bluish-green tint, and those of yellow and of blue were generally pink, showing considerable variations from the true complements. These and other anomalies led me to make some experiments with spectrum colours, which could be blended into uniform mixtures of known composition, instead

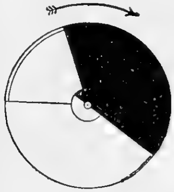


FIG. 1.

of with pigments, the apparatus employed for the purpose being a simple form of Sir Wm. Abney's well-known "colour-patch" apparatus. The experiments, of which a short account is here given, are fully described in a paper recently communicated to the Royal Society (*Proc. Roy. Soc.*, May 23).

A short pure spectrum, some three or four inches long, is projected, by means of a spectroscope collimator, a prism and an achromatic lens, upon an arrangement known as a "slit-screen." This consists of a wooden board having an oblong window over which slide three brass slit-frames carrying adjustable slits. The two outer slit-frames are attached to sliding shutters, which serve to cover such portions of the window right and left of the slit-frames as would otherwise be open to the light; the spaces between the middle slit-frame and the two outer ones are closed by opaque black ribbons, constituting miniature spring-roller blinds. Each slit-frame can be moved independently to any desired position and clamped by a set-screw. When it is necessary to use larger portions of the spectrum than can be transmitted by the slits, the slit-frames and their appurtenances are removed from the screen and the spectrum is dealt with by means of one or more thin metal plates, which are inserted into a second pair of guides fixed on the other side of the screen. Each of these guides has three parallel saw-cut grooves in it, so that plates sliding in different pairs of grooves may be made to overlap one another, and thus screens or openings of almost any desired width may be provided with very little trouble. The selected portions of the spectrum pass through the slits to a large lens, which projects upon a white screen the image of a circular aperture in a diaphragm placed just in front of the prism. This image, which is $1\frac{1}{2}$ or 2 cm. in diameter, constitutes the colour-patch; it is illuminated by a uniform mixture of the spectrum-rays transmitted by the slit-screen. When the wave-lengths of the light are to be determined a screen of ground glass is put in the place of the opaque white screen and the slit of a spectroscope is brought near the bright image on the glass. To produce a bright ground upon which to see the after-images a beam of white light, derived from the same electric arc as the spectrum, is directed upon the screen. The white light passes through the aperture of an iris-diaphragm, and a lens is placed to project an image of the aperture upon the screen. The "white-light disc" so formed is concentric with the colour-patch, and in most cases of slightly greater diameter.

In the path of the two beams of light illuminating the colour-patch and the white-light disc is placed a zinc disc having two apertures, one near the centre to admit the spectrum-rays, the other near the circumference to admit the white light. This is caused to turn about five times in a second, and the apertures are so arranged that the sequence of phenomena produced upon the screen may be as follows:—The colour-patch is projected for about 1/40 second, then it is extinguished and immediately succeeded by the white-light disc; this remains for 3/40 second, and is followed by an interval of darkness lasting 1/10 second, after which the colour-patch reappears and the cycle begins again. The appearance presented to the eye when the true colour of the patch is green is that of a purple disc surrounded by an annulus of flickering white. Other colours, of course, produce pulsative images of different hues. It is sometimes better to view the pulsative image directly by means of an eye-piece instead of receiving it upon a screen; two or three methods by which this can be effected are described in the paper.

Perhaps the most interesting of the various effects observed with this apparatus is one which appears to throw some light upon the origin of the pulsative image and to show why the true colour is so completely lost. It was noticed that when the white-light disc was made a little smaller than the colour-patch, the pulsative image, which was in this case of the same size as the white-light disc, was surrounded by a dark ring. This observation led me to make what is called in the paper the "black spot" experiment. A circular piece of tinfoil was gummed to a glass plate which was placed behind the iris-diaphragm, a sharply defined black spot being thus formed in the middle of the white-light disc, as indicated in Fig. 2, where the outer circle represents the white-light disc, the shaded circle the colour-patch, and the inner one the black spot upon the white-light disc. The diameter of the black spot was made, after several trials, 0·6 cm., or rather more than one-third of the diameter of the colour-patch. Suppose the colour-patch to be green. When the apparatus is worked, the patch becomes purple; the site of the black spot, being strongly illuminated five or six times in a second by green light, might be expected to appear green; but it remains perfectly black; no trace of a flicker of green light can be seen upon it. This induced blindness is most conspicuous when the light is green or yellow; it does not occur at all with extreme red or with violet light; nor does it generally occur if the luminosity of the colour-patch is reduced below a certain limit, that of the white-light disc remaining constant. A colour of feeble luminosity can be seen upon the black spot, while a brighter cannot, which is a paradox; and it was noticed that as soon as the spot became distinctly coloured, the pulsative image almost disappeared. Absence of colour from the black spot is essential for a good pulsative image.

It is clear that we have here an example of what I have called in other papers a border effect; in certain cases light has the power of exciting some action just outside the boundary of the image projected upon the retina. The black spot is, of course, merely a device for exhibiting in a convenient manner a border

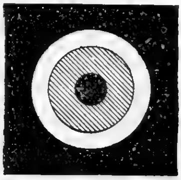

FIG. 2.

effect which extends for about half a degree beyond the white light impression. The experiment proves conclusively that, under the given conditions, white light has the power of restraining the visual sense-organs adjacent to those upon which the white light actually falls from responding to the green stimulus. This is of importance as indicating what occurs within the area illuminated by white light, for it would seem to follow *a fortiori* that the sense-organs which are directly acted upon by the white light must be similarly incapacitated from evoking any green sensation. In the formation of the pulsative image, then, it is not the fact, as generally believed, that the green sensation is produced for a moment and then swamped by a more powerful white one so completely as to escape notice; it actually never comes into existence at all. Nevertheless, the effects of fatigue by green are exhibited, and the physically white ground is seen as purple.

Only one possible explanation of the phenomenon has yet occurred to me. The facts can be accounted for in a perfectly simple manner if we suppose, as postulated by the theory of Hering, that there is an independent white sensation, and, further, that the latent period for a colour sensation is very much greater than that for white. For green, under the conditions of my experiments, the latent period would be at least 1/40 second, while for white it can hardly exceed 1/500 second, though the luminosity of the two may be as nearly as possible equal. The latent period for red is probably not very different from that for green under similar circumstances, while that for blue is considerably greater.

If in a darkened room a ray of green light is admitted to the eye for 1/40 second, one sees a flash of green; but, assuming that the suppositions which have been put forward are correct, the visible flash is not contemporaneous with the physical illumination. One does not begin to experience the green sensation until after the green ray which excited it has been shut off. What is actually perceived is, in fact, a positive after-image, the duration of which may be considerably longer than that of the stimulus. But if a sufficiently luminous white surface is presented to the eye immediately upon the expiration of the brief period of stimulation by green light, the after-image formed will not be positive, but negative, and the only colour perceived will be purple. The fatigue to which the negative image is due must have been set up during the latent period, when no image at all was actually perceived.

The formation of vivid pulsative images depends not only upon the latent period, but also upon persistence, luminosity, the duration of the primary impression and of the periods of light and darkness, and upon other circumstances. And the conditions which are best for some colours are not so for others. This fact obviously suggests that the pulsative image might afford a means of analysing compound colour-sensations, though so far it has been found available only to a limited extent. If the complete spectrum is projected upon the screen, it is seen at once that the blue-green pulsative image of the red, and the purple pulsative image of the green, are far more intense than the pulsative images of the yellow, the blue and the violet portions of the spectrum. Accordingly, if we make an orange colour-patch by combining red and yellow rays, it is not surprising to find that its pulsative image is blue-green, hardly differing at all from that of red, instead of sky-blue, which is the colour of the ordinary after-image of orange. Now the pulsative image of a patch illuminated by the simple orange rays of the spectrum is also found to be blue-green; hence the inference is clearly suggested that the spectral orange rays excite a red sensation. This particular fact will probably be regarded as one which needs no demonstration, but it is mentioned as an illustration of the proposed method of analysis. Several others in which the conclusions can be verified by trial might be given. Now it is noticed that under most ordinary conditions the purple pulsative image of green is more easily produced than that of any other colour. Under the same conditions we find that the pulsative images of yellow, of blue and of white are purple, and, assuming that the test referred to is a sound one, we conclude that yellow, blue and white all excite a green sensation. The proposed method of analysis may probably be carried much further than has yet been done.

This paper also contains an account of some new observations upon a class of phenomena to which I have drawn attention in a former communication (*Proc. Roy. Soc.*, vol. lx. p. 368; NATURE, vol. lv., p. 367). If the image of a white object is suddenly formed upon the retina after a period of darkness, the object generally appears to be surrounded for about one-tenth of a second by a narrow red border. It was noticed that when the bright object producing the image was looked at through variously coloured glasses the red border did not appear unless the glass used was capable of transmitting red light, and it was suggested that the phenomenon was due to sympathetic excitation of the "red nerve-fibres" lying immediately outside the portion of the retina directly affected by the radiation. The orange and yellow glasses employed for the observations referred to of course transmitted red light. Using the pulsative image apparatus with the eyepiece method, I now find that the simple red, orange and yellow rays of the spectrum, whether alone or in conjunction with any others, are competent to produce the red borders. The effect stops short at the beginning of the greenish-yellow. When blue and green rays are employed to illuminate the patch, either separately or in combination with each other, a blue-green border is produced. This is less intense than the red one before referred to, but if viewed in the manner described in the paper, the appearance of the green border due to pure spectral blue light of about $\lambda 4700$ is very striking. Violet produces no coloured border of the kind, and its admixture with other rays has no sensible effect upon the phenomenon. It can hardly be doubted that effects which occur, sympathetically as is suggested, just outside the boundary of the physical image, must also occur within the boundary; and if that is so, it follows that red, orange and yellow rays, nearly up to the beginning of the greenish-yellow, excite a red sensation, while green and blue excite a green sensation. There is at present no evidence of the same kind as to the existence of any other fundamental colour-sensation, though there must, of course, be at least one more.

The bearing of these border experiments upon theories of colour-vision is indicated in the paper. The following is among the most important points referred to. It is found that a comparatively small proportion of red mixed with other spectral rays results in the formation of a red border. According to the Young-Helmholtz theory, green spectral rays excite the fundamental red sensation to about the same extent as orange-red rays; yet no red border is formed by the green, though that formed by the orange-red is very strong. The natural deduction is that no red sensation is excited by green light.

As regards a different point which has been much debated, certain observations seem to be absolutely conclusive. According to Helmholtz the phenomena of simultaneous contrast are due entirely to mental judgment; according to Hering their origin is a physiological one. Experiments with one of the eyepiece methods, in which the apparent diameter of the pulsative image is about one-fourth of that of the white-light disc or field of view, seem to place the matter beyond dispute. If a purple pulsative image is produced from a strongly illuminated green colour-patch, the whole of the physically white field surrounding the patch appears to be purple. It cannot possibly be that the colour of the ground is a psychological effect resulting simply from contrast with green, for no green whatever is consciously perceived; the cause must necessarily be of a physiological nature. A similar effect is produced in an even more striking degree by blue and by violet colour-patches, the whole field appearing to be of the same hue as the pulsative images, namely orange and yellow. Phenomena of simultaneous contrast, as they are called, are therefore certainly not in all cases to be explained solely on psychological grounds.

The experiments which have been discussed establish nothing decisively in favour of either of the two principal theories of colour-vision. Some of the observations seem to support the Young-Helmholtz theory, others that of Hering; others, again, appear to indicate that neither theory in its present form is tenable. I venture to think that our knowledge of the subject might be materially increased by further experiments on the lines of those described.

SHELFORD BIDWELL.

THE SECOND INTERNATIONAL CONFERENCE FOR THE EXPLORATION OF THE SEA.

AFTER the International Conference which met at Stockholm in June 1899 for the consideration of a scheme for the systematic scientific study of fishery questions, it was proposed to meet again to complete the programmes at Christiania in the autumn of 1900. Various circumstances made it necessary to postpone the meeting, which eventually took place in the second week of May, when representatives of Germany, Belgium, Denmark, Finland, Great Britain, Norway, Holland, Russia and Sweden (the order is that adopted in the official *compte-rendu*—alphabetically in the French language), to the number of twenty-five, assembled in Christiania. The delegates included Dr. Herwig, president of the German Society for Promoting Sea-fisheries; Profs. Krümmel and Brandt of Kiel, and Profs. Heincke and Henking from Germany; Prof. Gilson of Louvain from Belgium; Captain Drechsel, Dr. Martin Knudsen and Dr. C. G. J. Petersen from Denmark; Dr. Nordqvist from Finland; Sir Colin Scott Moncrieff, Prof. D'Arcy Thompson, Dr. H. R. Mill and Mr. W. Garstang from Great Britain; Prof. Nansen and Dr. Hjort from Norway; Dr. P. P. C. Hoek from Holland; Dr. Knipovich from Russia; and Profs. Pettersson and Cleve, Dr. Trybom, Captain Maechel and Messrs. Wijkander and

Ekman from Sweden. Dr. H. H. Gran and Mr. K. V. Hammer acted as secretaries, and Profs. G. O. Sars and Mohn were invited to take part in the deliberations of the Conference.

The Norwegian Government received the Conference, the Prime Minister, Mr. Steen, acting as host, and very cordial messages were received from the King. The Municipality of Christiania also showed a lavish hospitality, and everything that could be done to promote the comfort of the delegates had been thought of and provided for. The meeting lasted from Monday, May 6, to Saturday, May 11, and the work—either in the full meetings, in committees, or, by no means least important, in personal conversation—was practically continuous from early morning till past midnight. The result was, on the whole, highly satisfactory; concessions had doubtless to be made all round, and some conclusions which might not be the best conceivable had to be accepted as the best obtainable; but the harmony of the international fellow-workers was unbroken, and during the whole meeting no question had ever to be put to the vote, agreement in every case being unanimous. The president of the Congress was Prof. Nansen, but the chief delegate of each of the chief countries represented presided each on one day.

The first work was the revision and completion of the Stockholm programme in its two divisions, which were known as the hydrographical and the biological. The former division, having been well elaborated at Stockholm, was easily disposed of, but the biological programme was entirely recast, several independent schemes of work which had been brought forward by the delegates having to be combined with the provisional programme. Next came the question of the organisation of the scheme of international research, which was only partially achieved. As it was necessary to refer several points to the various Governments concerned, it was decided that a committee of the vice-presidents should draft a series of recommendations to be sent in the same form to all the participating Governments, but not to be made public until a decision had been arrived at. Finally, a number of resolutions in the form of "pious opinions" were proposed and adopted.

The introductory clause of the official report, referring to the complete programme, runs: "Gonsidering that a rational exploitation of the sea should rest as far as possible on scientific inquiry, and considering that international cooperation is the best way of arriving at satisfactory results in this direction, especially if in the execution of the investigations it be kept constantly in view that their primary object is to promote and improve the fisheries through international agreements, this International Conference resolves to recommend to the States concerned the following scheme of investigations which should be carried out for a period of at least five years."

A. *Hydrographical Work.*—The object of this work is defined as the distinction of the different layers of water according to their geographical distribution, depth, temperature, salinity, dissolved gases, plankton (as an index of movement of water) and currents. To effect this object it is recommended that simultaneous observations should be made in the North Sea, English Channel, Baltic and North Atlantic along certain definite lines four times in the year, the middle point of the series of observations being in the first half of February, May, August and November. Instruments and methods are prescribed, and it is provided that meteorological as well as oceanographical observations shall be made, and that facilities shall be offered to the various national meteorological offices to cooperate in the study of the upper atmosphere at sea by the use of kites. The observations made on each of the international trips are to be plotted on synoptic charts at the earliest possible date after the return of the vessels. Stress is laid on the provisional nature of any determinations of salinity or density made at sea, and on the importance of carrying out such observations with the highest precision in laboratories on shore. The unit of depth is to be the metre, although it is allowable to add the depths in fathoms. The sea-mile is to be the unit of horizontal distance. For temperature, thermometers graduated in either centigrade or Fahrenheit degrees may be used, but all readings are to be reduced to centigrade for publication. While the new tables of the physical constants of sea-water prepared by Dr. Martin Knudsen, of Copenhagen, are to be employed, and are sufficient for their purpose, it is pointed out that it is desirable to have the existing tables of the absorption of atmospheric gases in sea-water revised. The mapping of the deposits on the sea-bed of the area to be studied is another desideratum to which attention is called. It is also pointed out that it is desirable to encourage regular observations of surface temperature and the collection of samples of surface water on board the steamers of regular lines which cross the area under investigation, a branch of work which has yielded excellent results in the hands of the Danish Meteorological Institute and in those of Mr. H. N. Dickson.

B. *The Biological Programme.*—Here two classes of recommendations are to be distinguished, those referring to obligatory work which each of the nations concerned is held bound to carry out, and to optional work, which, while desirable in order to complete the scheme of investigation, is not of such urgent importance. The areas in which the various nations are to work are suggested both for the hydrographical and the biological researches. Briefly put, they provide that the North Sea south of 58° N. should be divided by the meridian of 2° E., to the west of which British vessels should do the work, to the east of which Belgium, Holland, Germany and Denmark should undertake the sections lying off their own coasts. From 58° to 62° N., Great Britain, Norway and Denmark would share the work in the North Sea and North Atlantic. From 62° northward would be the sphere of interest of Norway in the Atlantic and of Russia off the Murman coast. The Baltic and its approaches would be dealt with by the three Scandinavian nations, together with Germany, Russia and Finland. No objection would be made to any of the research vessels extending their operations beyond the area allotted to them provided that the work in that area is not neglected.

The biology of food fishes is to be investigated in a comprehensive manner. The preparation of charts is recommended, showing the distribution in all their stages of growth of plaice, sole, turbot, cod, haddock and herring in the North and Arctic Seas, and of flounder, cod, sprat and herring in the Baltic. The observations to yield data for these charts are to be carried out as often as possible and with uniform trawls and other appliances, while the measurement and all particulars of the fish caught are to be recorded in a systematic and uniform manner.

In this respect optional researches are suggested on the life-history of food fishes with regard to their development, migrations and feeding places, all in connection with hydrographical conditions. To help towards this end the liberation of marked fish over wide areas and in large numbers is recommended. It is also considered useful to inquire as to whether fish of different species after being caught by various methods are likely to live if immediately liberated.

The study of the quantitative distribution of pelagic eggs, larvæ and young fishes is to be carried out as part of the routine work at all stations where physical observations are made, the method recommended being by vertical hauls of Hensen's large egg-net. As an optional extension of this part of the work the study of the eggs and young of food fishes may be continued in the intervals between the quarterly cruises, and experiments should be made on the artificial fertilisation and hatching of ova.

The researches of individual specialists are to be promoted by the collection of material as to the local varieties of plaice, herring and mackerel in the entire area subject to international investigation, and such researches may also be extended to include other useful species. The areas where undersized or immature fish specially abound are to be very carefully inquired into, and the quantity of such fish landed at the various ports as the result of various methods of fishing are to be ascertained. The statistical methods may be extended by the occasional sending out of experts on board fishing vessels to examine the catch as it is brought on board.

The study of plankton and bottom fauna is to be carried out by qualitative samples being collected as one of the routine operations at the various stations for hydrographic observations on the quarterly cruises, not merely from the surface, but by vertical hauls. Where possible, similar collections at other times and at regular shore stations is recommended as an optional extension. Quantitative hauls with Hensen's plankton-net are also recommended, the material collected being offered for examination to specialists who may be willing to undertake the work of quantitative determination. Endeavours should be made with suitable apparatus to investigate the organisms which inhabit the lowest water layers immediately above the bottom. The macroscopic animal and plant life of the bottom should also be studied, with special reference to the nutrition of food fishes. Among the optional researches which are suggested with reference to the bottom fauna are observations on the bacteria of the bottom and of the water immediately above.

The last section of the biological programme deals with the importance of elaborating fishery statistics so as to yield data for constructing maps of the fishing grounds, and for determining the influence of physical conditions on fish.

With regard to the apparatus to be used in these observations, Prof. Nansen, Dr. Hjort and Mr. Garstang gave a demonstration on board the *Isbjorn* in Christiania fjord of the insulating water-bottle as used for exact measurements of temperature, and of various forms of closing tow-nets.

C. *Organisation of the International Council, Central Bureau and International Laboratory.*—The organisation which is to put the elaborate system of observations recommended by the Conference into operation and to record and work out the result is obviously the most important part of the whole scheme, as upon its successful working depends the whole of the success of the attempt at concerted action. The International Council is thus described :—

"The permanent International Council shall consist of commissioners elected by the Governments interested. Each Government should appoint two commissioners who may be represented at meetings by substitutes, and may be accompanied by experts who, however, shall not be competent to vote.

"The council elects its president and vice-president and appoints all officials of the Central Bureau. Should the general secretary represent hydrographic science, one of his principal assistants should be a biologist, and *vice versa*. The other assistant shall preferably be experienced in statistical work. . . .

"It will be for the Governments concerned to decide among themselves the amount of the contributions to the Central Organisation. The expenses of the Central Organisation are approximately estimated at 4800*l*. yearly. . . .

"The purpose of the Central Bureau will be :

"To give uniform directions for the hydrographic and biological researches in accordance with the resolutions drawn up in the programme of the present Conference, or in accordance with such modifications as may be introduced later with the consent of the States represented.

"To undertake such particular work as may be entrusted to it by the participating Governments.

"To publish periodical bulletins which shall contain the actual data obtained in the cruises of all the participating States at the earliest possible date, and also such other papers as may prove useful in coordinating the international work. . . .

"The site of the Central Bureau, to be decided by the Governments concerned, shall at the same time be the residence of the general secretary.

"The purpose of the International Laboratory shall be :—

"To control apparatus and to ensure uniformity of methods. The various apparatus and instruments now used for oceanic research should be examined in order to settle which are the most trustworthy. Experiments may also be made to improve the apparatus and instruments or to construct new and better ones.

"The water-samples sent by the workers of the participating States are to be analysed and examined at the Central Laboratory, from which also samples of standard water should be provided. . . .

"The International Laboratory is subordinate to the Central Council, to which its accounts shall be rendered. Its operations shall be reported to the Central Bureau.

"The site of the Central Laboratory shall be decided by the Governments concerned, and should be conveniently situated for oceanic researches."

The relations of the Central Bureau and the International Laboratory will probably be somewhat difficult to define, and the success of the two practically independent institutions will depend on the strength and tact of the International Council, the selection of the members of which will devolve upon the Governments associating themselves with the work.

Resolutions.—The general resolutions adopted by the Conference included an expression of the desirability of the provision of at least one steamer specially adapted for marine research by each of the participating States. This is so self-evident as hardly to require statement. Norway already possesses such a vessel in the *Michael Sars*, which has already done excellent work under Dr. Hjort; Russia has also equipped a vessel for fishery observations, and Germany has sanctioned a very carefully-planned ship, involving some very important innovations, which is now, we believe, almost ready to be launched. To carry out the British share of the work properly two vessels will be required, and for so promising a field of practical application of science it seems reasonable to hope that they will be provided.

The opinion is formally expressed that the Central Bureau should commence operations as soon as possible, and not later than the beginning of next year, while the first set of international cruises should take place not later than May 1902. To make this possible it is recommended that the International Council should meet in Copenhagen as soon as the participating Governments decide to accept the programme of the Conference.

A resolution expresses sympathy with the efforts of Governments which are endeavouring in the face of difficulties from foreign trawlers to preserve an area, such, *e.g.*, as the Moray firth, from fishing operations, for experimental purposes. Another thanks Dr. Knudsen for his recently published hydrographical tables, in which he gives a new determination of the physical constants of sea-water. The remaining resolutions suggest methods for graphically representing the dynamics of oceanic movements, approve of the inclusion of observations on fresh-water lakes simultaneous with, and similar to, those on the sea, and point out the importance for deep-sea fisheries and for weather forecasts of bringing the Faeroes and Iceland into the telegraphic system of Europe.

It remains now for the Governments of the northern marine nations of Europe to give effect to this carefully planned scheme.

H. R. M.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following is the text of the speech delivered by Prof. Love in presenting Dr. P. L. Sclater for the degree of D.Sc. *honoris causa*, on June 20:—

Adest Philippus Lutley Sclater, Sodalis Societatis Regalis, Magister Artium in Academia nostra, Philosophiæ Doctor in Bonnensi, Collegii Corporis Christi Socius honoris causa creatus. Qui vir, ut primos eius annos et incunabula laudis breviter præstringam, si quis alius, vere Wiccamicus vocandus est, cum non solum ipse et postea duo eius filii sed olim pater atque avus in illustrissima Schola Beatæ Mariæ de Winton instituti sint. Ita per quattuor hominum ætates huius domus nomen in annalibus Wiccamicis notissimum. Nostræ mox Academiæ particeps et Collegii Corporis Christi alumnus duos fere et quinquaginta abhinc annos graduatus est.

In ὀρνιθολογίᾳ quam vocant hic profecto familiam ducit : hoc gubernante Societas Zoologica Britannica laude maxima floret; horti autem Zoologici Londinenses nullis usquam cedunt. Quod ad doctrinam exquisitiorem et rei Zoologicæ peritiam attinet, illud potissimum dixerim, hunc regionum Zoologicarum naturam et limites primum perspexisse cum regionibus sex constitutis, Palæarctica, Nearctica, Neotropicali, Æthiopica, Orientali, Australi, orbem terræ non hominum civitatibus sed ferarum generibus partiretur. Quam rationem quinquaginta fere abhinc annos excogitatam plurimi ita emendare et corrigere conati sunt, quo in numero erat ipse Huxley, vir in hoc genere doctrinæ præstantissimus, ut etiam hodie probatissima et naturæ convenientissima esse videatur. Multa docuit hic vir ingeniosissimus quæ adhuc omnium iudicio comprobantur, velut Africæ septentrionalia harenosæ Nomadum solitudini superiacentia re vera Palæarctica esse atque Europæ affinia; Arabiæ autem meridiana in regionem Africanam sive Æthiopicam cadere : de duabus etiam Americæ continentibus felicissime monuit, hanc ab illa divioi, non isthmo illo Panamensi, sed septentrionali Mexicæ latere, cum ultra citraque hanc quasi lineam accuratissime descriptam diversissima ferarum genera inveniantur.

SIR HENRY ROSCOE, F.R.S., has been elected Vice-Chancellor of the University of London for the ensuing year.

PROF. J. G. MACGREGOR, F.R.S., professor of physics in Dalhousie College, Halifax, Nova Scotia, has been elected to succeed Prof. Tait as professor of physics in the University of Edinburgh.

DR. F. H. NEWMAN, of the Royal College of Science, London, has been appointed director of technical education and principal of Tullie House, Carlisle. Tullie House consists of a public library, museum and school of art. It is the intention of the committee to build a technical school at an early date, the land having been already purchased. Dr. Newman commences his duties on July 1.

REPLYING to a question as to the terms of reference to the Royal Commission on University Education in Ireland, in the House of Commons on Thursday last, Mr. Balfour said they were as follows:—"To inquire into the present condition of the higher general and technical education available in Ireland outside Trinity College, Dublin, and to report as to what reforms, if any, are desirable in order to render that education adequate to the needs of the Irish people." The chairman is Lord Robertson, and among the other members are Profs. Ewing, Rücker and J. Lorrain Smith.

IN opening an exhibition of practical work done in connection with the City and Guilds of London Institute, at the Imperial Institute, Lord Avebury referred to the dependence of technological instruction upon the sound teaching of science, and some defects of school work in general, when considered from an educational point of view. He pointed out that our great public schools were bound under the regulations of the Public School Commission to give one-tenth of the marks in all examinations to science and one-tenth to modern languages. But this obligation was systematically ignored. At the greatest of our schools there were twenty-eight classical masters, thirteen mathematical, and only four science masters for more than 900 boys. The University of London, which he had the great honour of representing in Parliament for more than twenty years, had always taken a leading part in endeavouring to secure for science its proper place in our educational system. It was the first to give science degrees. It made a knowledge of science an obligatory part of the matriculation examination, that no University degree should be given to any one who, taking the line that literature, science and mathematics were necessary elements in any well-though-out education, was not well grounded in all three. It was difficult to over-estimate the important and beneficial effect which this had had on our secondary schools, and he deeply regretted that it had been proposed to drop science out of the list of obligatory subjects in the matriculation examination. It was greatly to be hoped that the Senate would not adopt a recommendation which was so retrograde and so opposed to the whole traditions of the University, and which he did not hesitate to say would be a national misfortune. The Chambers of Commerce did not wish, nor, he was sure, did scientific men wish, to exclude classics. What they pleaded for was that science, the knowledge of the beautiful world in which we lived, should not be excluded.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, June.—The number opens with an account of the proceedings at the two April meetings of the Society. The Chicago section held its meeting at the University of Chicago on April 6. Ten papers were read, and abstracts of the papers are edited by Prof. T. F. Holgate. The other meeting was held in New York City on April 27. To relieve the increasing burden of administration, Dr. Edward Kasner was appointed assistant secretary, to serve until February 1902. This gentleman reports the proceedings and gives abstracts of several of the seventeen papers which were communicated.—The value of

$$\int_0^{\frac{\pi}{2}}(\log 2\cos\phi)^m\phi^n d\phi$$

is a notelet which was read before the April (1899) meeting of the Society by Prof. F. Morley.—Dr. Kasner's paper on the algebraic potential curves (read February 23, 1901) has for its object the derivation of the characteristic geometric properties of a class of curves which are of interest in connection with the theory of equations and of the potential function. Analytically, these curves are obtained by equating to zero the rational integral solutions $\phi(x, y)$ of Laplace's equation

$$\Delta\phi \equiv \frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} = 0,$$

or, what is equivalent, the real (or imaginary) parts of the rational integral functions of $x+iy$.—Various geometric properties are given in Briot and Bouquet's "Théorie des Fonctions Elliptiques" (book iv. chap. ii.), but none are completely characteristic. The several sections treat of (1) apolarity with respect to a point pair, (2) polar properties of potential curves, (3) focal properties, (4) the asymptotes, and (5) the connection with the theory of equations. Several useful references are given in footnotes.—The reviews are of Steinmetz's "Alternating Current Phenomena," by J. B. Whitehead, jun., and of de Tannenberg's "Leçons Nouvelles sur les Applications Géométriques du Calcul Differential," by L. P. Eisenhart.—The usual information follows in the notes and new publications.

American Journal of Science, June.—The new spectrum, by S. P. Langley. A short account of the methods adopted for mapping the spectrum in the ultra-red. The paper is accompanied with a map of this spectrum for wave-lengths between 0·76 μ and 5·3 μ.—On the rival theories of cosmogony, by O. Fisher. A discussion of the meteoric and nebular hypotheses. A study of some American fossil Cycads. Part iv. On the microsporangiate fructification of Cycadeoides, by G. R. Wieland. It was suggested in a previous paper that the sorus-bearing axis is a series of twelve fused leaves or fronds with their sorus-bearing pinnacles turned inwards. More extended study of additional material in a far superior state of preservation has confirmed the above hypothesis as a correct one.—Studies of Eocene mammalia in the Marsh collection in the Peabody Museum, by J. L. Wortman. A continuation of a previous paper.—On the cæsium-antimonious fluorides and some other double halides of antimony, by H. L. Wells and F. J. Metzger. A description of the mode of preparation and properties of five double salts of the composition $CsF.3SbF_3$, $CsF.2SbF_3$, $4CsF.7SbF_3$, $CsF.SbF_3$ and $2CsF.SbF_3$, mohawkite, by J. W. Richards.—The life-work of Prof. H. A. Rowland, by H. F. Reid.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 28.—"On the Results of Chilling Copper-Tin Alloys." By C. T. Heycock and F. H. Neville.

Sir W. Roberts-Austen and Dr. Stansfield have shown that the cooling curves of many copper-tin alloys exhibit well-marked "arrest points," or halts in the cooling due to the evolution of heat. From the temperatures at which these halts occur it is certain that many important changes take place long after the alloy has apparently become solid. Thus the authors find that an alloy of the composition $Cu_{81}Sn_{19}$ shows well-marked halts in cooling at the temperatures 754° C., 743° C., 558° C. and 490° C., the temperature at which solidification appears complete being but little below the second of the numbers. The exact nature of the changes causing the lower halts has until recently been obscure, but Prof. Roozeboom, by his paper on "Binary Systems Producing Mixed Crystals," has thrown much light on these phenomena.

The present paper is an attempt to apply Roozeboom's theory to the copper-tin alloys.

The authors, by slowly cooling small ingots of alloy to definite temperatures near the "arrest points" of the cooling curve, and then suddenly chilling them by immersion in water, have been able to prevent the subsequent changes due to slow cooling from taking place. The structures formed during the slow cooling down to the moment of chilling were thus fixed and could be examined.

It follows from Roozeboom's theory that in the solidification of a liquid mixture that can form mixed crystals the crystals first formed will generally differ in composition from the liquid, but that these crystals will change in composition as the solidification proceeds, and that in many cases at temperatures slightly below that of complete solidification the solid will consist of a uniform mass of mixed crystals. He further discusses the possibility of the solid solution thus formed breaking up into separate phases by crystallisation in the solid at lower temperature.

This paper contains photographs of three chills of the same alloy, $Cu_{81}Sn_{19}$, which illustrate these changes. In the first case the alloy was chilled at 740° C. (Fig. 1), while it was still partly fluid, and the photograph shows large primary combs much richer in copper than the mother substance.

Another portion of the same alloy was chilled at 630° C. (Fig. 2), a temperature at least 100 degrees below that of solidification. Even when etched or attacked in a variety of ways this sample shows no detail indicating any difference of composition; it appears to be homogeneous, or very nearly so. It has reached the stage of uniform mixed crystals.

Another fragment was chilled at 500° C. (Fig. 3), close to the lowest "arrest point." The photograph shows that crystallisation has taken place in the solid solution and that a substance rich in tin has crystallised in rosettes and bands, leaving a mother substance rich in copper.

These alloys, after polishing, were prepared for photography by slightly oxidising the surface by gently heating them in air, the temperatures needed to bring out the pattern in this way being far below those at which changes in the structure of the alloy occur. When treated thus, the parts rich in copper oxidise, and therefore darken, more rapidly than those rich in tin, hence the dark parts in the photographs correspond to matter rich in copper, and *vice versa.*

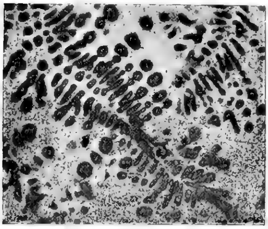

FIG. 1.—Chilled at 740°.

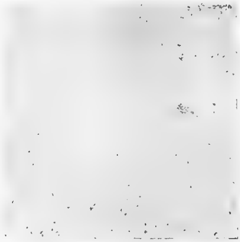

FIG. 2.—Chilled at 630°.

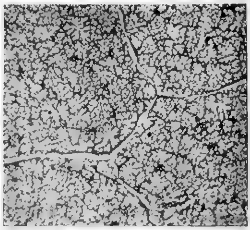

FIG. 3.—Chilled at 500°.

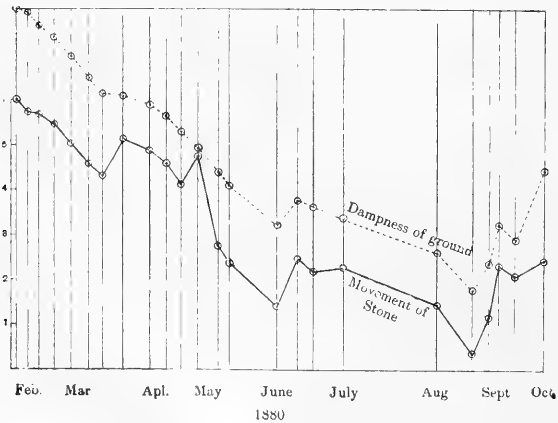
The authors have found similar, though sometimes more complex, phenomena throughout a considerable range of composition. The results lead to the conclusion that it is unwise to interpret a freezing curve by the examination of slowly-cooled alloys only.

May 2.—"On the Small Vertical Movements of a Stone laid on the Surface of the Ground." By Horace Darwin. Communicated by Clement Reid, F.R.S.

The experiments described in this paper were undertaken originally to measure accurately the downward movement of a stone caused by earthworms. The upward and downward movements due to varying moisture of the soil and to frost were found to be much larger than was expected. These movements,



interesting in themselves, increase the difficulty of accurately determining the movement due to the action of earthworms.

To obtain a fixed point from which to measure the displacement of the stone a rod was driven into the ground to a depth of 2·63 metres. The top of this rod was the point from which all measurements were taken.

A circular stone about 460 mm. in diameter and about 57 mm. thick, weighing about 23 kilos., was placed on the ground with the rod projecting through a hole in its centre.

A screw micrometer graduated to ·01 mm. was used. The screw was turned until its end just touched the end of the rod; owing to an unforeseen cause of error the measurements were not trustworthy to the last place of decimals. However, when care was taken to avoid this error, consecutive readings agreed to less than this amount, showing that the method was capable of greater accuracy than was required. Errors caused by the growth of the roots of a tree near the stone, swelling of the soil due to dampness, and the expansion of the rod from change of temperature are discussed.

The movements of the stone are represented graphically; the figure reproduces one of the diagrams.

The curve marked "Movement of Stone" represents the up and down movements of the stone from February 19 to October 9, 1880, due to the varying dampness of the ground.

The points corresponding to each observation are surrounded by a small circle; their vertical distance apart is proportional to the movement of the stone, each division of the scale representing 1 mm.; the horizontal distance apart is proportional time.

The curve shown by the dotted line roughly represents the dampness of the soil. Moisture is assumed to leave the soil at a uniform rate; the ordinates are proportional to the rainfall less this assumed amount evaporated or drained away; both quantities are calculated from February 19. The curves follow each other, showing that the stone fell as the soil became dryer and rose again with rain. In May there is a marked exception; the most probable explanation is an error in reading the micrometer. The total downward movement from February 19 to September 7 is 5·6 mm. On another occasion artificially wetting the ground raised the stone 0·6 mm.

Measurements taken in the winters of 1878 and 1886 show that the stone sank about 2·2 mm. per year. Measurements were also taken in the summer of most years from 1878 to 1896. The downward movement was not regular, and it is shown that this also is partially due to the varying dampness of the soil. From 1878 to 1887 the stone sank on the average about 2·3 mm. per year, and from 1887 to 1896 about ·36 mm. per year.

The effect of frost is to raise the stone; it fell rapidly during a thaw—on one occasion 2·3 mm. in 4 hours 40 minutes.

June 6.—"The Measurement of Ionic Velocities in Aqueous Solution, and the Existence of Complex Ions." By B. D. Steele, B.Sc., 1851 Exhibition Scholar (Melbourne). Communicated by Prof. Ramsay, F.R.S.

The method of measuring ionic velocities described by Masson has been extended in such a manner that, by the present method, the use of gelatin solution and of coloured indicators is not necessary.

An aqueous solution of the salt to be measured is enclosed between two partitions of gelatin which contain the indicator ions in solution, the apparatus being always so arranged that the heavier solution lies underneath the lighter. On the passage of the current the ions of the measured solution move away from the jelly, followed at either end by the indicator ions; the boundary is quite visible in consequence of the difference in refractive index of the two solutions. The velocity of movement of the margins is measured by means of a cathetometer, and the ratio of the margin velocities gives at once the ratio of the ionic velocities.

The velocities of a large number of ions at different concentrations of different salts have been calculated, and the velocities of the hydrogen and hydroxyl ions have been also measured, with the following results:—

	Found.	Calculated.
OH in KOH, 0·5 N	0·001435	0·00145
,, NaOH, 0·2 N	0·00158	0·00152
H in HNO_3, 0·2 N	0·00282 / 0·00272	0·00280

The ratio of the current, as measured by the galvanometer, to that calculated from the velocity of the margins in the manner indicated by Masson, is found to be equal to unity only for a few salts of the type of potassium chloride; for other salts this ratio has a value in some cases greater, in others less, than 1. The same irregularity has been previously pointed out by Masson for the gelatin solutions of the sulphates of magnesium and lithium.

The attempt is made to explain this deviation from the requirements of theory, and also the difficulty that Kohlrausch is unable to assign to dyad elements any value for the specific ionic velocity, which is the same when calculated from the measurements of different salts of the same metal, by the assumption, first advanced by Hittorf, that, in concentrated solutions of these salts ionisation takes place in such a manner that there are formed complex ions in addition to simple ones; and the conclusion is drawn that, in all cases where any considerable change in transport number occurs with changes in concentration, complex ions are present to a greater or less extent.

Zoological Society, June 4.—Dr. W. T. Blanford, F.R.S., vice-president, in the chair.—A communication by Dr. R. Broom, on the structure and affinities of the Anomodont genus Udenodon, was read. It contained an account of a number of specimens from the Lower Karoo beds of Pearston, South Africa, which the author referred to the Dicynodont genus Udenodon [Oudenodon]. One of these, a small skull, was shortly described as the type of a new species (*U. gracilis*).—A communication was read from Mr. Oldfield Thomas, F.R.S., in which he gave the history of the specimen of *Rhinoceros lasiotis*, Sclater (which had lived for thirty-two years in the Society's Gardens), and stated that he was of opinion that it was not deserving of specific rank, but should be considered rather as a subspecies of *R. sumatrensis*. The generic nomenclature of the rhinoceros was also examined, and it was proposed that the existing species of this family should be divided into three generic divisions—Rhinoceros (to include *R. unicornis* and *R. sondaicus*), Dicerorhinus (to include *R. sumatrensis* and *R. sumatrensis lasiotis*), and Diceros (to include *R. simus* and *R. bicornis*). It was shown that, if it were found necessary to divide the species *R. simus* and *R. bicornis*, the former, with its fossil allies, should bear the name Coelodonta.—Mr. G. A. Boulenger, F.R.S., read a paper on a small collection of fishes from the Victoria Nyanza which had been made by the order of Sir H. H. Johnston, K.C.B. Six species were enumerated and remarked upon, two of which (*Labeo victorianus* and *Discognathus johnstoni*) were described as new.—Mr. F. E. Beddard, F.R.S., described six new species of earthworms of the genus Benhamia from Tropical Africa.—A communication was read from Mr. J. G. Millais containing some notes on the capture of a specimen of Bechstein's Bat (*Vespertilio bechsteini*) in the neighbourhood of Henley-on-Thames. So far as was known, this was only the second occurrence of this species recorded in Great Britain.—Mr. H. R. Hogg read a paper on the Australian and New-Zealandian spiders of the suborder Mygalomorphæ. The author adopted the nomenclature of M. Simon, and stated that of the seven subfamilies of this suborder into which M. Simon had divided it, six were represented in Australia and New Zealand, the only absentee being the Paratropidinæ of South America.

Entomological Society, June 5.—The Rev. Canon W. W. Fowler, president, in the chair.—Mr. G. C. Champion exhibited a male specimen of *Odontaeus mobilicornis*, one of the rarest of British beetles, captured at Woking on May 28.—Mr. R. McLachlan exhibited four specimens of a curious bug of the genus Henicocephalus received from Mr. G. V. Hudson of Wellington, New Zealand, not previously noticed in that country. Mr. Champion said that Henicocephalus was generally recognised as a type in itself of a family, and Mr. Kirkaldy that it was much commoner than generally supposed. It was probably only an aberrant form of the Reduviidæ, having no stridulating apparatus on the prosternum.—Mr. C. P. Pickett exhibited varieties of *Smerinthus tiliae* bred during May 1900-1.—Mr. C. G. Barrett exhibited imagines, cocoons, pupa skins, and also water-colour sketches of larvæ, reared and drawn by Miss Frances Barrett, at Buntingville, Pondoland, S. Africa.—Dr. A. Jefferis Turner exhibited specimens of Australian wood-boring Lepidoptera belonging to four different families. They included examples of Pyralidæ, Gelechidæ, Cossidæ and Hepialidæ.—Mr. H. Goss exhibited for Mr. Ernest Ardron, of Colombo, Ceylon, two specimens of a species of Phyllium (Phasmidæ). They bore an extraordinary resemblance to leaves. He also showed three varieties of the male of *Melitaea Cinxia*, which he had taken on May 27 and 28 at Niton, Isle of Wight.—Mr. C. O. Waterhouse exhibited two new genera and species of Coleoptera recently described by him in the *Ann. and Mag. Nat. Hist.* from Rio Janeiro. One belonged to the aberrant Prisnidæ (*Pathocerus Wagneri*); the other (*Tetraphalerus Wagneri*) belonged to the Cupesidæ, and was remarkable for the form of its head. He also exhibited ♂ and ♀ of the curious Scarabæid, *Glyphoderes sterquilinus*, Westw., from North Argentina.—Mr. H. St. J. Donisthorpe exhibited a glove burnt by discharges of formic acid in the nests of *Formica rufa*. Prof. Poulton said that the discharges collected in tubes fluctuated greatly in strength, the strongest yielding a proportion of sixty to seventy per cent. of anhydrous acid. The discharge of *Dicranura vinula* showed a strength of about forty-five per cent.—Mr. W. Schaus communicated "A Revision of the American Notodontidæ," and Mr. H. St. J. Donisthorpe read a paper on cases of protective resemblance, mimicry, &c, in British Coleoptera.

Linnean Society, June 6. Mr. W. Currathers, F.R.S., vice-president, in the chair.—The adjourned debate was resumed on Mr. H. M. Bernard's paper on the necessity for a provisional nomenclature for those forms of life which cannot be at once arranged in a natural system.—The following resolutions were proposed by Mr. Bernard: (1) That the Linnean method of naming is well adapted for indicating affinity, and should be used for that purpose; (2) that allied forms whose affinities are not clear should be designated by some provisional method of naming; (3) that the method proposed by the author appears to promise enough to justify its temporary application to the Anthozoa. Mr. H. Groves moved as an amendment to the first resolution to omit all after the word "naming," and to substitute "is adequate for the present needs of zoology and botany." This was seconded by Dr. P. L. Sclater. The discussion was continued in order to elicit the views of those present on the resolutions proposed by Mr. Bernard, but no vote was taken.

Anthropological Institute, June 11.—Dr. A. C. Haddon, F.R.S., president, in the chair. Mr. Morton Middleton exhibited, on behalf of the South American Missionary Society, a large series of implements and other objects, including swan gullet necklaces, whalebone snares, featherwork, &c., from the Yahgans of Tierra del Fuego, and introduced Mrs. Burleigh, who spent some fifteen years among the Yahgans, and gave a number of additional data in regard to them.—Mr. G. Coffey read a paper on Irish copper celts.

Mathematical Society, June 13.—Dr. Hobson, F.R.S., president, in the chair.—The theory of Cauchy's principal values (ii.), by Mr. G. H. Hardy.—On the general form of three rational cubes whose sum is a cube, by Prof. Steggall.—Invariants of curves on the same surface, in the neighbourhood of a common tangent line, by Mr. T. Stuart.—Short impromptu communications were made by Dr. Macaulay (2) and Lieut.-Colonel Cunningham, R.E.

DUBLIN.

Royal Irish Academy, June 10.—The president in the chair.—On the creeping of liquids and tension of mixtures, by Dr. Fred T. Trouton, F.R.S. A number of experiments were described which showed that in order for a liquid to be capable of creeping over solid surfaces it must be a mixture. Ordinary paraffin, for example, does so, but a pure paraffin will not creep. It can be made to do so, however, by the addition of a suitable liquid. The added liquid must be more volatile, and must reduce the surface tension. This can be the case not only with liquids of lower surface tension, but also with liquids of higher surface tension when added in small quantities. For experiments on mixtures of liquids in general showed that the surface tension of a mixture is always less than the percentage calculated value. Thus an actual depression of the surface tension is in most cases produced by adding a liquid of higher surface tension. For this reason there are few liquids by the addition of which the creeping of, say, ordinary paraffin may be prevented, the requisite being a more volatile liquid with a very high surface tension.

EDINBURGH.

Mathematical Society, June 14.—Mr. J. W. Butters, president, in the chair. The following papers were read: (1) Note on an extension of Abel's theorem on the continuity of a power series, by Prof. Gibson; (2) The diffraction of plane waves incident obliquely on a semi-infinite plane, by Dr. Carslaw.

PARIS.

Academy of Sciences, June 17.—M. Fouqué in the chair.—Researches on chemical equilibria. The formation of insoluble phosphates by double decomposition; disodium hydrogen phosphate and silver nitrate, by M. Berthelot. In the reaction between silver nitrate and ordinary sodium phosphate, the total precipitation of the silver as phosphate takes place only when the two salts react in equimolecular proportions. Precipitates formed in the presence of an excess of sodium phosphate contain a certain amount of sodium, probably in the form of a sodium silver phosphate, which cannot be removed by prolonged washing.—On some new syntheses effected by means of molecules containing the methylene group associated with one or two negative radicles. The action of epichlorhydrin and epibromhydrin upon the sodium derivatives of benzoylacetic esters, by M. Haller. The chlorine or bromine atom is not eliminated in these reactions, but an addition product is formed. Thus epichlorhydrin with benzoylacetic ester gives a new ketolactone, the properties and reactions of which are given.—M. Maupais was nominated a correspondent for the section of anatomy and zoology in the place of the late M. Marion.—Some new nebulæ discovered at the Observatory of Paris, by M. G. Bigourdan. Positions and descriptions of twenty-one new nebulæ.—On the employment of the stereoscope in astronomy, by M. Maurice Hamy. Remarks on some possible applications of the stereoscope in astronomy, with applications to the study of the motions of stars by the Doppler-Fizeau principle, to eclipses of the sun with special reference to the internal movements of the chromosphere, and to the internal movements of nebulæ.—The equations and fundamental properties of reciprocal autopolar figures in the plane and in space, by M. Rabut.—On Fourier's series, by M. A. Hurwitz.—On the application of the theory of elasticity to the calculation of bent rectangular beams, by M. Mesnager.—On electromotive forces of contact and the theory of ions, by M. E. Rothé. An experimental study with a Lippmann capillary electrometer in which the solution could be readily changed, the solutions used being sulphuric and hydrochloric acids of varying strengths. The variations of electromotive force thus observed were compared with those calculated from the ionic hypothesis, the agreement in the case of the weak solutions being satisfactory.—The capillary constants of organic liquids, by MM. Ph. A. Guye and A. Baud. Measurements by the method of Ramsay and Shields of the capillary constants of phenetol, anisol, ethyl acetate, nitrobenzene, benzonitrile and metacresol. In all these substances, with the exception of metacresol, the value of the constant K exceeds the number 2·121 admitted by Ramsay and Shields as the value for a non-polymerised liquid, but the author adduces reasons for supposing that this does not necessarily mean that these substances are in a polymerised state.—On a new element, europium, by M. Eug. Demarçay. By a prolonged fractionation of samarium it has been possible to isolate the oxide of an element, apparently distinct from samarium, and which is capable of giving rise to the so-called anomalous ray, discovered by Crookes in the fluorescent spectrum of samarium. It is also identical with the element provisionally named *Zε* by de Boisbaudran. The name europium is proposed for this substance, with the symbol Eu = 151 about.—On the chlorobromides of thallium, by M. V. Thomas. The methods of preparation and the properties of two chlorobromides of thallium are described, having the compositions $Tl_3Cl_2Br_4$, and $TlClBr$.—The reactions of acetylene with cuprous chloride dissolved in a neutral solution of potassium chloride, by M. R. Chavastelon. The action of acetylene upon a neutral saturated solution of cuprous chloride gives the same results as when the solution is acid or alkaline.—The separation of nickel and cobalt by the electrolytic method, by M. Dmitri Balachowski. From a solution containing both nickel and cobalt salts to which ammonium thiocyanate, urea, acetic acid, and a little ammonia have been added, it has been found possible by careful attention to the voltage, and especially to the amperage, to completely separate the nickel, which comes down apparently as a sulphide. By then altering the voltage and the strength of the current the cobalt can be thrown out.—Study of contact action on the secondary and tertiary alcohols, by M. A. Trillat.—On the floral organogenesis of the disciflora, by M. L. Beille.—Diffusion in gelatin, by M. S. Leduc.—On the presence of carbon monoxide in the blood of the newly-born, by M. Maurice Nicloux. In ten estimations of the amount of carbon monoxide in the blood of a newly-born animal the amount found varied between ·08 c.c. to ·14 c.c. of CO from 100 c.c. of blood, with a mean of 0·11 c.c. The amounts were estimated by the amount of iodine set free from iodic acid, and from this reaction and the fact that the gas is totally absorbed by hæmoglobin it is quite certain that the gas is really CO.—On a biochemical differentiation of the two principal ferments of vinegar, by MM. Gab. Bertrand and R. Sazerac. The two species, *Mycoderma aceti* and *Bacterium xylinum*, can be distinguished by their different oxidising power towards glycerin.—On the extrapolar electrotonic currents in nerves without myeline, by M. Mendelssohn.—On the reaction time in different races and social conditions, by M. Louis Lapicque. The average reaction time of Europeans was found to be 0·15 second, of Hindoos 0·22 second and of Andaman Islanders 0·19 second.—The influence of the lethecines of the egg upon the nutritive changes, by MM. A. Desgrez and A. Zaky.—On the use of yeast as a means of finding out communications between sheets of water, by M. P. Miquel.

William Huggins

THURSDAY, JULY 4, 1901.

SCIENTIFIC WORTHIES.

XXXIII.—Sir William Huggins, K.C.B.

FAR from the noisy centre of London, in Upper Tulse Hill, there is a quiet house. The welcome accorded to one who has the good fortune to enter at its hospitable doors reminds one of Philemon and Baucis, and the visitor amidst the artistic decorations of the house feels transplanted into another world. In the garden extending far behind the house one sees the astronomical observatory with its dome, and recognises that this is the house of a man of science, not an artist.

We are in the dwelling of Sir William Huggins, on whom the English scientific world has lately conferred the highest honour by electing him President of the Royal Society.

Sir William has been in the happy position of being able to follow his scientific inclinations without being limited by official duties. After some hesitation he decided on Astronomy and built his observatory, the description of which is contained in his first scientific publication.

At that time, 1856, astronomy was chiefly confined to measurements of the positions of celestial bodies, but a few years later quite a new field was opened out by the great work of Kirchhoff and Bunsen, and it was Sir William Huggins who first introduced the new knowledge into astronomy and fertilised it.

The new science, Astrophysics, is in great part his work, and indeed I hardly know of another example where the history of the development of a science so nearly coincides with the story of one man.

Sir William had the good fortune to come on virgin ground everywhere, so that every observation meant a great and fertile discovery; but it is his merit that he was the first to recognise the importance of the new discovery, that he invented the best methods and instruments, and that he united in himself the necessary knowledge of Astronomy, Physics and Chemistry.

The so-called "good fortune" really plays a small part in great discoveries.

> "Wie sich Verstand und Glück verketten.
> Das sehn die Thoren niemals ein;
> Wenn sie den Stein der Weisen hätten,
> Der Weise mangette dem Stein,"

as Goethe says.

As soon as the news of Kirchhoff and Bunsen's discovery reached Huggins, he saw clearly that the application of spectrum analysis to the heavenly bodies was his field of research, and in this field he has laboured during the succeeding forty years with indefatigable ardour and never wanting success. His first researches were made in conjunction with W. A. Miller, Professor of Chemistry at King's College, who had been a worker in spectrum analysis for fifteen years.

As their first result they were able to send to the Royal Society in 1863 a Report on the Spectra of Stars. It is true Fraunhofer (1814), and Lamont and Donati (1860) had seen star spectra, but the method of observation employed by Huggins was quite different, being difficult and more fruitful. It was not at all sufficient now to see lines in the spectra of stars, but their chemical origin had to be determined; and therefore the light-gathering objective prism could no longer be used, but after the method of Kirchhoff and Bunsen a slit and comparison prism were employed. As thereby the spectrum is enormously weakened and has scarcely any breadth, Huggins introduced the cylindrical lens.

Very soon the insufficient knowledge of the spectra of the elements became obvious, and Huggins undertook with great success the task of determining the position of the lines of as many elements as possible in the visible part of the spectrum. The results were invaluable at that time, and even now, after the introduction of instruments so much more accurate, they are of value.

The year 1864 brought a great triumph for Huggins in the discovery that many of the nebulæ gave spectra consisting of bright lines. This fact was of enormous importance theoretically in consideration of the Kant-Laplace hypothesis of the genesis of the universe. Also of great importance were the observations on the new star in Corona, published by Huggins in 1866. Here he saw for the first time bright and dark lines combined in the same spectrum, and as the explanation he suggested an enormous convulsion of the star, excited, perhaps, by the approach or collision of a dark star.

In this and the following years he found opportunity to observe spectra of comets. Although they were too weak to enable him to pronounce any definite opinion on these mysterious phenomena, they sufficed to show that the light was partly reflected and partly emitted by the comets themselves. This result was confirmed when in 1868 the bright comet of Brorsen appeared, and Huggins found that its spectrum contained bright bands, which he recognised as belonging to carbon.

In the short period of five years Sir William had been the pioneer over a vast territory. Fixed stars, nebulæ, comets and even a new star were forced to disclose their mysteries. It would seem that the possibility of absolutely new discoveries were now excluded, that only the more detailed study of the same phenomena was left to science. But the genius of Huggins found new work for the spectroscope. Doppler's principle, that the wave-length of light is altered when the observer and source of light alter their distance apart, was certainly recognised as true, but nobody had thought of applying it to the extremely important case of stellar motion in the line of sight. Huggins was the first to do this, in 1868, with a new instrument, the result of some years of consideration.

The fertility of this new method, the beautiful and unexpected results which it has given in later years, is well known, and there is no doubt that in the future it will be the means of revealing to us much that at the present time remains mysterious.

At about the same time Huggins had tried to observe the prominences of the sun in the absence of an eclipse. He solved the problem and published an account of his methods, so that although he was preceded in the observation itself by Janssen and Lockyer, his high reputation was sustained. Immediately afterwards we find, as his contribution to the development of the subject, a description of a method for not only determining the chemical constitution, but also the actual shape of the protuberances.

In still another region Huggins has been a pioneer. As early as 1864 he had tried to photograph star spectra, but with his small and imperfect apparatus he only obtained spectra without lines. He did not, however, lose sight of the problem, and after the invention of dry plates he constructed a spectrograph out of rock crystal and Iceland spar which, with a Cassegrain telescope, gave the well-known beautiful spectra, among the novelties of which may be mentioned the revelation for the first time of the ultra-violet series of hydrogen.

The continued application of photography to the spectra of the various celestial bodies, the discovery of innumerable important and interesting results, occupy the following decades of a laborious life. It is impossible to follow in detail the whole of Huggins' achievements, contained as they are in nearly a hundred publications. To do so would require volumes, not one short article; nor is it possible to point out how Huggins was enabled by the construction of his spectroscopes to produce those excellent photographs which have excited our admiration during the last twenty years. There does not exist, I believe, any stellar spectrograph which does not involve in its construction ideas taken from Huggins' models. One obtains a superficial insight into the immense progress made by Huggins in the photography of stellar spectra in the book which he has presented to science under the title "Atlas of Representative Stellar Spectra," by Sir William and Lady Huggins. This and all the later publications of Sir William Huggins are signed also by Lady Huggins, in whom Sir William has found an "able and enthusiastic assistant." It would therefore be unjust not to mention Lady Huggins in a description of Sir William's work.

This necessarily very short and incomplete review, in which only a few of the most important discoveries could receive mention, while many others, such as, for instance, the detection of the band spectrum of water-vapour, had to be passed over, will show how productive and beneficent to science his life has been. The child to whom he gave life, Astrophysics, has been the object of his care and attention and has now developed into a strong and beautiful man.

The father can look with pride upon his child, and well may he be happy to see the progress which has been made and the number who now devote their energy and knowledge to this part of science.

But above all Huggins is distinguished by the extraordinary accuracy of all his publications. He has always been very cautious in drawing conclusions from observations; with an enthusiastic heart he has combined a cool head. He has scarcely ever been forced to retract or modify a statement, and therefore his views are universally accepted and his authority remains unrivalled, which I think to be the highest reward and greatest honour to which a scientific man can attain.

William Huggins was born in London, 1824. He built his private observatory in 1856, became President of the Royal Astronomical Society, 1876; President of the British Association, 1891; President of the Royal Society, 1900. He has received a Royal medal, the Rumford medal and the Copley medal from the Royal Society, and two medals from the Royal Astronomical Society. He married Miss Margaret Murray, of Dublin, in 1875.

H. KAYSER.

ENGLAND'S NEGLECT OF SCIENCE.

England's Neglect of Science. By Prof. Perry, F.R.S. Pp. 113. (London: T. Fisher Unwin, 1900.) Price 2s. 6d.

UNDER the above title Prof. Perry publishes a collection of seven short papers dealing with several questions relating to the position of science and the method of teaching it in England. The little book itself takes its title from the second of these papers, an article which appeared in NATURE in July 1900.

The subject is one of such great magnitude and intricacy that it is scarcely possible for a private individual to bring a sufficient knowledge of details to bear upon it. Nothing short of a commission of men of science would suffice to collect the mass of statistics which is necessary for the complete discussion of the shortcomings of England in her relation to scientific education. We must, therefore, be content to deal with it from a few points of view only, most of these being indicated by Prof. Perry himself.

Prof. Perry is well known to be, like several of his colleagues in science, dissatisfied with the position of science in England, with its influence in the affairs of State, and with the provision made for its support and development. When, however, he speaks of "England's" neglect of science it would be well if he made a distinction between England as a *nation* and England as a *Government.* It is not true that the English people as a whole are indifferent to the supreme claims of science in the modern world, but it is most unfortunately true that the men placed by the people at the heads of the Government departments are sadly wanting in a knowledge of science, and are, as a result, almost indifferent to its interests. Indeed, at the hands of the typical English Government official the profession of scientific education shares with science itself the results of this indifference. There is unquestionably a marked want of sympathy on the part of our Government officials with all those whose business it is to spread scientific knowledge among the people. What is the cause of this? The simple and direct answer is—the public schools. These institutions—some of them venerable as to age, all of them venerable as to ideas—supply almost exclusively the professional politicians to whose care the interests of the great departments of the Government are committed, and in all of them the dominant educational ideals are classical and mediæval. The career of the English professional politician is fairly well stereotyped. A classical education at one of the fashionable public schools, followed by something very similar at an ancient University, accompanied probably by the pursuit of some branch of athletics, and almost certainly by a continuous neglect of all branches of science, is the typical training of the heads of English officialdom. Neither science nor those whose profession is the teaching of science can hope for much encouragement from rulers developed by such a system as this. As for zeal in the promotion of invention or discovery before the thing aimed at becomes a visible and established fact, let no man look to an English Government department for that.

If the root of the public evil—England's *official* neglect of science—is to be found in the mediævalism of the public schools, the cause of the evil in the schools themselves is, to a great extent, to be sought in the *classical clerics* who are almost invariably placed over them; for very few of the head masters are men who have received any training in modern science. It is doubtful, however, if this is the *whole* cause of the unscientific character of the public schools; for in most, if not in all, of them some science is taught, and in several there are to be found laboratories erected at a cost of many thousands of pounds. But the "modern side" does not rank high in the estimation of the public school, and science is dignified with the name of "stinks." Modern science seems to fit the English public school about as well as a new piece fits an old garment; and if a knowledge of science is a desirable and important thing in the upper classes of this country, the whole system of the public schools must be overhauled.

Prof. Perry himself says some plain words on this matter (p. 14):—

"Much of the evil we suffer from is due to our average young men being pitchforked into works where they get no instruction, as soon as they leave school. If ordinary school education were worth the name, and if schoolmasters can be brought to see that we do not live in the fifteenth century, if boys were really taught to think for themselves through common sense training in natural science, things would not be so bad. But the average boy leaves an English school with no power to think for himself, and with less than no knowledge of natural science, and he learns what is called mathematics in such a fashion that he hates the sight of a mathematical expression all his life after."

It is most true, as Prof. Perry said recently in a lecture to working men at South Kensington, that, under our present unscientific educational system, "the most prominent Englishmen understand nothing of those sciences which are transforming all the conditions of civilisation."

But it is sometimes said in reply to those who complain of the want of scientific knowledge and sympathy on the part of the heads of Government departments, "you must remember that the real managers of these departments are not the heads but the permanent subordinate officials." This may be so, but it is very doubtful if we are any better off in the hands of these permanent officials. The higher appointments of the Home Civil Service are now filled by candidates selected from those who have successfully passed the examination for the Indian Civil Service; and an investigation will show that about 80 per cent. of the successful candidates obtain their places by means of classics; thus the chances of an infusion of scientific thought into the Government offices are not great.

It is vain to say, as some of our politicians are fond of telling us, that England must depend for the encouragement of science upon private benefactions and not upon Government support; a Government which adopts such a principle is simply shirking one of the greatest of its obligations.

A striking illustration of the unsympathetic attitude of English Governments towards men of science, and more especially the teachers of science, is always furnished by a perusal of the "New Year" and "Birthday" list of honours. Peerages and baronetcies are given somewhat freely to brewers and political supporters, and a perfect shower of knighthoods and minor honours to a host of officials of whose achievements the nation in general is profoundly ignorant. Now and then a Kelvin, a Lister, or a Stokes appears; but, though England possesses scientific inventors and discoverers in large numbers, very few of them are thought worthy of national recognition.

Setting aside the radical weakness of our school system—its mediævalism—there are some defects that are more easily rectified; and among these Prof. Perry specially emphasises the orthodox procedure in the teaching of mathematics. Nothing but the ingrained conservatism of the English people would continue to base a boy's first knowledge of geometry on the peculiar language and the abstract reasoning of Euclid. Euclid, as has been repeatedly and vainly pointed out, was never written for boys; Euclid is difficult and not particularly well ordered; but Euclid is *classical*, and therefore Euclid is acceptable to the public schools, notwithstanding the fact that most boys waste years in attempting to acquire the somewhat grotesque language in which Euclidean logic is couched without attaining a real knowledge of even the nature of *an angle!* To know how Euclid shapes in the minds of the majority of schoolboys, to understand what a keen logical sense and expression they acquire from it by years of practice, one must conduct a public examination in the subject—and then not despair of the human race.

Prof. Perry does not confine his attack on our system of teaching mathematics to Euclid; he holds that a boy's scientific knowledge, generally, should not be primarily based upon abstract reasoning.

"Why not let a boy jump over all the Euclidean philosophy of geometry and assume even the 47th proposition to be true? Why not let him replace the second and fifth books of Euclid by a page of simple algebra . . . ?"

Some such procedure as Prof. Perry here indicates is really the key to improvement in our scientific teaching; and the objections which his proposal is likely to meet are met by him with a certain forcible humour:

"Because the embryo passes through all the stages of development of its ancestors, a boy in the nineteenth century must be taught according to all the systems ever in use and in the same order of time. Think of compelling emigrants to pass to America through Cuba, because Cuba was discovered first. Think of making boys learn Latin and Greek before they can write English, because Latin and Greek were the only languages in which there was a literature known to Englishmen 450 years ago!"

And this is, substantially, our procedure. Prof. Perry's remedy for our waste of time in mathematical teaching is contained in his advocacy of what he calls "Practical Mathematics," which may be described as a short cut to all the most important results and methods of science without the preliminary passage through a train of abstract reasoning in the old order—not, we presume, that the abstract reasoning is to be abolished altogether, but that it will come later and more easily when the results which it was originally employed to establish have become familiar practical truths by experience and measurement. This contention of Prof. Perry's does not, of course, agree with the pure *a priori* nature of mathematical reasoning hitherto accepted as orthodox truth. Indeed, it is not uncommon to hear even some scientific men objecting to such a principle as Prof. Perry's in some such terms as these: "Mathematics is primarily an education of the mind, and it must be regarded as an end in itself; the object of education is not the short and rapid attainment of practically useful knowledge, but the *cultivation of thought*." The simple answer to this is that, in view of the pressure of competition in the affairs of practical science, we cannot afford to take things in the old leisurely manner. Moreover, as already said, the re-ordering of our mathematical teaching according to the plan sketched by Prof. Perry in his chapter on "Practical Mathematics" does not involve, by any means, the *abolition* of abstract reasoning, but the *postponement* of it until the mind of the pupil is in the best condition to employ it.

We cannot afford space to discuss Prof. Perry's syllabus of practical mathematics in detail, but we may say that all those who have either the good fortune or the bad, according to the scene of their labours, to be employed in the teaching of mathematics, will find their work facilitated by adopting the system of graphic representation and graphic solutions so strongly advocated by Prof. Perry. The graphic method of solution of problems otherwise insoluble constitutes a wonderful interest both for the pupil and for the teacher; but, unfortunately, this fact is as yet very imperfectly recognised.

There is one branch of the question of school teaching which is scarcely noticed by Prof. Perry—the question of the preparatory school. The growth of the preparatory school in England within the last twenty years is most remarkable. This somewhat costly institution is, as a rule, an exact copy of the public school. The methods, the language, and, above all, the athletic ideals and aims of both are the same. The unscientific career in the greater institution is carefully initiated and cultivated in the less. Now, although nearly every branch of physical science is full of facts, principles and methods, the experimental illustration of which would awaken a far greater interest in the mind of a young boy than can be awakened by Greek or Latin grammar, the teaching of the elements of physical science in the preparatory stage of youth is almost unknown. There is a great deal of the elementary, but very important, portion of the science of electricity which every boy of the age of twelve (or less) should know, and could learn with no difficulty whatever; but he is kept rigorously aloof from all such knowledge, and we see him at the age of thirteen or fourteen fully equipped at his preparatory school for his public school exhibition or scholarship, absolutely ignorant of every electrical fact in existence.

This refers, of course, to boys of the better classes—those who look forward to a public school education. Prof. Perry remarks on the subject (p. 95):—

"I see no reason why the principles of physics should not be intimately known to every child who has passed the age of twelve years. . . . An examination of the work carried on in the model national schools in Ireland will show that in many cases children of eleven and twelve years possess a fair knowledge of physics and chemistry, and when they do not possess this knowledge it will be found that too much attention has been paid to Euclid and grammar, and perhaps practical geometry has not been studied at all."

In taking leave of Prof. Perry's suggestive little book, we would say that if the average English parent is content that his son should be brought up according to the classical model of the public school, with its athletic ideals and that superior "tone" with which it is generally credited, it might not be proper for any one to interfere with his choice; but when we reflect that these classical institutions are those in which our political rulers acquire their training and form their ideals, without appreciable modification by a subsequent career in an old University, the whole nation has a right to complain. The professional politician is apt to look down upon the professors of science; and until science makes its presence felt in the Government of the country by having eminent scientific men in its councils, we shall have to continue to deplore "England's neglect of science."

GEORGE M. MINCHIN.

GRANT DUFF'S NOTES FROM A DIARY.

Notes from a Diary, 1889–1891. By Sir Mountstuart E. Grant Duff. Vol. i. Pp. viii + 287. Vol. ii. Pp. 272. (London: Murray, 1901.) Price 18*s*.

IT might truly be said of Sir Mountstuart Grant Duff as was once said of Van Dyck, "During these years all noble England passed before him and remained immortal." He is a member of the best clubs—the

Athenæum, the Literary Society, The Club, &c.; he was for many years in the House of Commons, has been Under-Secretary for India, Under-Secretary for the Colonies, Governor of Madras, &c. He has thus had great opportunities, of which he has made the most. As was said of Archbishop Williams, he has "read the best, heard the best, conferred with the best; excribed, committed to memory, disputed; and had some work continually upon the loom."

Moreover, he has not only striven, and successfully, to know the ablest statesmen, literary men and men of science in our own country, but abroad also—V. Cousin, Hubner, B. de St. Hilaire, J. Simon, Taine, and many others were among his friends. The diary of such a man could not but be most interesting.

He has acted on the motto from Renan, which he places at the head of his first volume: "On ne doit jamais écrire que de ce qu'on aime. L'oubli et le silence sont la punition qu'on inflige à ce qu'on a trouvé laid ou commun dans la promenade à travers la vie."

Several of his reviewers have expressed the opinion that there are parts of the book which might have been spared, but I doubt whether they would have agreed which should be left out. The botany has been more than once suggested for omission; but to that I for one should, of course, demur. Sir Mountstuart has always loved natural history, and as a statesman has rendered valuable services to botany. He quotes with natural pleasure Sir J. Hooker's dedication to him of the 117th vol. of the *Botanical Magazine*, "as a slight acknowledgment of the valuable services which you rendered to botany and horticulture when Under-Secretary of State, first for India and then for the Colonies, and lately when Governor of the Madras Presidency; to which I would add, in memory of our long friendship, and our delightful rambles at home and abroad, in pursuit of our favourite science."

The whole book is full of good stories, of wise and witty sayings, of which, of course, we can only give a very small sample; for instance,

"—— is forty years old, Gladstone is eighty years young."

"Talleyrand remarks that 'Les affections lointaines sont un asile pour la pensée.'"

"Lady Alwyne Compton 'divided biography into autobiography, and ought—not to biography.'"

"Evarts, being asked if he was going to the funeral of a man whom he very much disliked, said, 'No, I shall not attend, but I quite approve of it.'"

"Woman was made after Man, and has been after him ever since."

"Two young ladies discussed for some time the colour of the Devil, when at last one said, 'I think you will *find* that I am right, dear.'"

"As Lady Blennerhassett left the dining-room she asked me, 'Do you like women's votes?' and supplied the answer, 'I like women who de-vote themselves.'"

"Mrs. Montgomery said of a friend, 'She gives me the impression of having been in the garden of Paradise before the Fall, but, having got a hint of what was about to happen, escaped before the coming of Original Sin.'"

While imbued with the scientific spirit, and thoroughly sympathising with the most liberal views of Stanley, Jowett and Renan, Sir Mountstuart Grant Duff has a deep feeling of reverence for the mysteries of existence. We meet again and again evidence of the profound impression made upon him by the récit d'une sœur; he speaks with affectionate veneration of Newman, and he tells us how much he valued the benediction which he sent him when he was starting for his Madras Government.

In his view of our religion he seems (though he does not expressly say so) to agree with Renan that

"Il ne sera remplacé que par un idéal supérieur; il est roi pour longtemps encore. Que dis-je? Sa beauté est éternelle, son règne n'aura pas de fin. L'Eglise a été dépassée, et s'est dépassée elle-même; le Christ n'a pas été dépassé."

The diary ends with an admirable address to the girls of the High School, Oxford. He gives them excellent advice: "Remember that to live a great and beautiful life is a far higher achievement than anything that can be done in life save by the very rarest genius."

He dwells first on what they should not learn—no higher arithmetic, no mathematics—no learning by heart, except some masterpieces, which should be kept up—no English grammar. Latin and Greek only as rewards.

Next what they should learn—reading, writing, drawing, book-keeping, needlework, cooking, enough French and German to read an ordinary book, some short treatise on logic, and enough music to enable them to enjoy the work of others, and some knowledge of the world in which we live. Lastly, he recommends them all to read four books—the "Meditations of Marcus Aurelius," the "De Imitatione," Gracian's "Oraculo Manual," and "Joubert's Pensées."

No one, I think, will put Sir Mountstuart's book down without a kindly feeling for the author, and a hope that he might have his characteristic wish to "come back every ten years, say for three weeks, just at this season, when the lilac, laburnum and wild hyacinth are out, to see how you are (the world is) getting on."

AVEBURY.

FIELD EXPERIMENTS ON WHEAT.

Cultura del Frumento, 1899-1900. *xiii Anno di cultura continua del Frumento e del Granturco.* By Prof. Italo Giglioli. Pp. xx+159. (Portici: Premiato Stab. Tipografico Vesuviano, 1901.)

IN the year 1887 Prof. Italo Giglioli, director of the R. Scuola Superiore Agraria di Portici, commenced a series of experiments on the growth of wheat under various manurial conditions at Suessola, in the Province of Caserta. The experiments are maintained by the Neapolitan Association of Landowners and Farmers, assisted, during the last few years, by grants from the Department of Agriculture.

The experimental field covers nearly two acres, and is divided by paths into 123 plots of about 45 square metres each. In most cases two or more plots (sometimes six or even twelve plots) receive the same treatment, and in this way the actual number of distinct experiments is reduced to forty-five. The produce of each of the 123 plots is, however, separately cut and weighed.

In the first year of the experiments wheat alone was grown, but owing to very favourable climatic conditions, and the character of the soil, it was subsequently found possible to grow two cereal crops each season—wheat from November to July and maize from July to October. The results show that the average yield of wheat is a good deal lower than in England, for instance; but the two crops taken together furnish an amount of grain in excess of the yields of the single crops obtained in England, Germany and the north of France. The character of the climate of Suessola is further illustrated by the fact that Rabi wheat from Oudh tends to give increased crops when grown in this district. English wheat, on the other hand, was found to deteriorate.

As regards the effect of the different manures on the wheat crop, horse-dung with sulphate of ammonia, applied in the spring, gave the highest yield, both of grain and straw. Sulphate of ammonia alone, applied in the spring, gave a higher yield of grain, but less straw than when applied partly in the autumn and partly in the spring; this result is attributed to the excessive rainfall during the winter months. With nitrate of soda there was a much lower yield of grain and rather less straw than with sulphate of ammonia. In accordance with what has been observed at Rothamsted and at Woburn, Giglioli obtained a greater weight per bushel under the influence of sulphate of ammonia than with nitrate of soda. Both these manures proved to be very effective when applied in conjunction with horse-dung. In this connection it may be mentioned that, quite recently, Hiltner has found that when humous sandy soil and heavy soil were inoculated with certain denitrifying organisms an increased production of oats was obtained. These results lend support to the view, now very generally accepted, that, in practice, the danger of any considerable loss of nitrogen under the influence of denitrifying organisms has been a good deal over-estimated.

Basic slag alone very considerably increased the yield of wheat grain; a still further increase in grain and also in straw was obtained when horse manure, or a mixture of sulphate of ammonia, nitrate of soda and potassium chloride were applied in addition to basic slag. Exclusively nitrogenous manures in addition to basic slag yielded about the same amount of grain, but more straw, than basic slag alone. Mineral superphosphate gave less satisfactory results than basic slag. Leucite, which occurs in large quantities in Italy, especially Roccamonfina, increased the yield of wheat when applied along with nitrate of soda; in conjunction with basic slag and nitrogenous manures, it produced about the same effect as potassium chloride under the same conditions.

Some interesting results are recorded on the effect of manganese dioxide, applied with various manures. These experiments, which have now been continued for three years, tend to show, in the majority of cases, that manganese dioxide in some way benefits the wheat crop. Further experiments on the subject, in which other crops, such as mangels, might be included, are desirable.

Electro-culture experiments with wheat manured with horse-dung showed a distinct gain both in grain and in straw when atmospheric electricity was employed, the increase in grain being relatively the greater. Voltaic electricity produced a still more marked effect, and increased the yield both of grain and straw by about 10 per cent.

It has not been possible within the limits of this short notice to give much more than a general indication of the lines of Prof. Giglioli's carefully conducted series of experiments, which, as time goes on, cannot fail to gain in interest and value. The present Report is well arranged for reference, and contains excellent bibliographies of some of the subjects investigated. The second Report, dealing with the results of the maize experiments, will, it is hoped, be ready before very long. N. H. J. M.

EARTH CURRENT MEASUREMENTS.

Die Erdströme im Deutschen Reichstelegraphengebiet und ihr zusammenhang mit den Erdmagnetischen Erscheinungen. By Dr. B. Weinstein. Pp. vi+78, and Atlas to ditto. (Brunswick: Friedrich Vieweg and Son, 1900.) Price, Mk. 4.

OF late years, when the interests of the electric railway and tramway have clashed with those of the observatories in which magnetic and earth current measurements are made, it has frequently been urged by the opponents of the observatories that they continue year after year accumulating data of which no use is ever made. Unfortunately, in most cases, owing, no doubt, to the very inadequate staff and multitudinous duties they have to perform, there is a certain amount of truth in this contention. It must, however, not be forgotten that the material is always available and can be worked up at any future date, while if the observations are interrupted, for however short a time, no amount of money or trouble expended at a subsequent time can replace the missing measurements. In this connection it is, therefore, with considerable pleasure that we welcome this pamphlet of nearly eighty pages, together with a quarto volume of curves, which give an account of the measurements made of the earth current curves obtained in two lines, one running between Berlin and Dresden, and the other between Berlin and Thorn during the epoch 1884–1888.

The author considers, in the first place, the manner in which the earth currents change, and in the second place to what extent these changes are connected with simultaneous changes in the terrestrial magnetic field.

In order to investigate the periodic changes in the earth currents, the ordinates of the photographic curves were measured for every hour and the means were used to calculate the coefficient of a Fourier expansion. The agreement between the values of the coefficients derived from the means for the various years is quite surprising considering the irregularity which one associates with all earth current phenomena.

The two lines being very nearly at right angles, and making the supposition that the current measured in the line is proportional to the current which traverses the earth, the author is able to calculate for each hour of the day the azimuth in which the current is flowing through the earth's crust. He compares the azimuth of this resultant current with the azimuth of the trace of the vertical plane passing through the sun. The results of these measurements, as well as a consideration of the way in which the earth currents change in magnitude and direction for the various months of the year, are all most clearly shown by means of vector diagrams. Vector diagrams are also given to show the changes in the earth's magnetic field for various stations, and a comparison between the two classes of curves shows a striking resemblance between their more salient features. It is quite impossible in such a notice as this to deal with the mass of data contained in the work, but we have no doubt that all interested in the fascinating subject of terrestrial magnetism will read the book with very great interest and feel, with the reviewer, that a great debt is due to Dr. Weinstein for the enormous amount of labour he has expended and for the satisfactory manner in which he has carried out his task.

OUR BOOK SHELF.

The Life of the Bee. By Maurice Maeterlinck. Translated by Alfred Sutro. Pp. 348. (London: George Allen, 1901.) 5*s*. net.

So far as our present knowledge extends, there are only four groups of animals which live in organised and more or less civilised communities at all resembling our own; and these are not mammals, or even vertebrates, as we might have been inclined to imagine *a priori*, but insects —ants, wasps, bees and termites. Hitherto entomologists have been inclined to award the palm of intelligence to the ants, but M. Maeterlinck thinks that the intelligence of the hive-bee has been somewhat underrated, at least as regards the readiness with which bees accept and adapt themselves to new conditions; and he also argues, as others have done before him, that the proceedings of human beings would probably appear far less intelligent to beings as far removed from man as man is from the bee, than do those of a bee-hive to ourselves. The book is not a romance in which bees are anthropomorphised, but an actual presentation of the life-history of the bee, and it appears to be abreast of the latest knowledge on the subject. The subject is discussed from the standpoint of a moderate agnosticism, and is interspersed with philosophical reflections on the various phases of bee-life as compared with human life, and of the equal mystery surrounding both. A fairly good list of some of the principal works on bees, in which English writers hold a very prominent position, is given at the end of the book. Incidentally, we are sorry to see the very unfavourable picture drawn, in § 94, of the peasantry of Normandy. We hope and believe that it is by no means universally applicable to the peasantry of other countries, including our own. As the work has doubtless been translated under the supervision of the author, it is probable that his meaning has been fairly grasped and expressed by his translator. As a specimen of the style of the book we may quote a short passage from pp. 302, 303: "Were an observer of a hundred and fifty times our height, and about seven hundred and fifty times our importance (these being the relations of stature and weight in which we stand to the humble honey-fly), one who knew not our language, and was endowed with senses totally different from our own; were such an one to have been studying us, he would recognise certain curious material transformations in the course of the last two-thirds of the century, but would be totally unable to form any conception of our moral, social, political, economic or religious problems." Here and there (as in the case of the word "importance" in the above passage) we find a word used which seems, from the context, hardly to express the author's meaning in English; and more rarely we find a technical error, as where *Sphinx Atropos* is once called a "butterfly" instead of a moth. These trifling defects can easily be remedied in a second edition, and in no way impair the interest of a book of somewhat unusual character. We should add that M. Maeterlinck is himself a practical bee-keeper (as well as an eminent man of literature), and has therefore the advantage of an acquaintance at first-hand with the general subject. W. F. K.

West African Studies. By Mary H. Kingsley. Second Edition, with Additional Chapters. Pp. xxxii + 507. (London: Macmillan and Co., Limited, 1901). Price 7*s*. 6*d*.

WE are glad that a popular edition of the late Miss Kingsley's "West African Studies" has been issued at a price which puts it within the reach of the humblest student; for, as we pointed out in our review of the first edition some twelve months ago, the book is worthy of the widest and closest study not only by students of primitive religion, but also by all those who have the interest of our West African colonies at heart. Before she started for South Africa Miss Kingsley had arranged to issue this edition, and though she did not live to see it through the press, the task of editing the volume has been completed by Mr. George Macmillan on the lines already approved by her. The new edition differs from the old by the omission of the appendices by the Comte de Cardi and Mr. John Harford, which, when once on record, are always accessible to the student, while their absence of general interest would have hardly justified their inclusion in the present reprint. In their place room has thus been found for a number of lectures and magazine articles which Miss Kingsley delivered and wrote shortly before her death. The new matter includes her Hibbert lecture on "African Law and Religion," some articles on "Property in West Africa," reprinted from the *Morning Post*, and two lectures on Imperialism in general and "Imperialism in West Africa." The bulk of the volume has been reprinted in its original form.

Mr. George Macmillan has prefixed an interesting introductory notice to the second edition, in the course of which he sketches the circumstances which led Miss Kingsley to undertake the researches which will always identify her name with West Africa; at the same time he gives a brief sketch of her character. We cannot refrain from quoting one passage, which seems to us to explain her personality more concisely and more truly than any other appreciation of her that we have yet seen.

"Not long after her death a friend who knew her well, a man qualified to speak by long experience of men and affairs, summed up the rare combination of overflowing sympathy and intellectual grasp which constituted at once the power and the charm of Mary Kingsley by saying that 'she had the brain of a man and the heart of a woman.' Speaking of her time in West Africa, she herself said, on one occasion, that she was 'doing odd jobs, and trying to understand things!' The phrase was characteristically modest, but here again we see how the heart which inspired the 'jobs,' which were always for some one else's benefit, worked deliberately in concert with the brain which was ever 'trying to understand things.' Together the two phrases strike the keynote of her life."

The Use of Words in Reasoning. By Alfred Sidgwick. Pp. xi + 370. (London: Adam and Charles Black 1901.) 7*s*. 6*d*. net.

THE name of Mr. Alfred Sidgwick is a sufficient guarantee that this book will be of value to all who are genuinely interested in the processes of reasoning, and desire, without plunging into the shadowy land where logic merges itself in metaphysical speculation, to extend their research somewhat further than a study of the formal logic of the schools will take them. The old-fashioned formal logic, "Pass Mods" logic, is, in fact, of little use except as a mental discipline for University passmen; others will hardly find in the ancient jingle of *Barbara Celarent Darii Ferioque prioris*, with its many combinations and permutations, a sufficient explanation of all the phenomena of reasoning. As Mr. Sidgwick says (p. 338): "Logic . . . might really quicken our sense of bad reasoning; but what formal logic does is only to quicken it in the least interesting and important direction, and so to draw our attention away from the serious dangers. In fact, we agree . . . that a man may improve his reasoning habits by studying logic, but we would lay rather more stress on the condition, 'if he has the sense to know when formalities are out of place.'" Mr. Sidgwick sketches the main points of his objections to the scholastic logic in a way which can be easily followed; and in his last chapter, on "How Logic might be Taught," he gives a succinct and simple explanation of the main processes which are employed in reasonable hinking.

Holidays in Eastern Counties. Edited by Percy Lindley. Pp. 96. (London: 30 Fleet Street, E.C.)

IT would be easy to select many places in which to spend a restful holiday from those described and attractively illustrated in this guide-book. The eastern counties possess many points of interest to students of nature and archæology, and are worth exploration in the days of leisure.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Vertical Light-beam through the Setting Sun.

THE not very frequently observed appearance of a vertical pillar of light through the sun when nearly setting was so very remarkably distinct and bright this evening as to deserve, perhaps, a particular description. I observed it in the Victoria Park, near Hackney, in the north-eastern part of London, from about 7h. 30m. to 8h. 10m. p.m. The setting sun at the first of those times was about 7° or 8° above the horizon, and its light was but little dimmed and tinged with yellow yet, by faint cirro-stratus cloud-bands among which it was shining, which ruled the western sky obliquely downwards towards a point of the horizon about 45° northwards from the sun. The light-column then, when I first saw it, was yellow coloured, bright and narrow at the base, but more diffused above, where it could be traced up to a length of 5° or 6°, while its base rested upon, or extended very little, if at all, below the sun. The summit grew narrower and higher as the sun descended lower, while the base became brighter and followed the sun down until, at about ten or fifteen minutes to 8, the sun was much dulled in light and assumed an orange yellow colour in entering a bank of haze about 5° from the horizon. Below that altitude the light-column's base never descended; but when at about 8 p.m. the sun had acquired the magnificent appearance of a great crimson disc, still about 2°, or some four of its diameters, clear from the level park horizon, the tall column shone beautifully above it as a perfectly straight, vertical, narrow streak of light about the sun's apparent diameter in width and 8° or 10° in length (from about altitude 5° to altitude 15°, and very faintly rather higher), bright yellow at its base, but becoming insensibly whiter and dimmer, without lateral diffusion till lost across the faint cloud-streaks which seemed here and there just visibly to lengthen it and very faintly extend it somewhat higher. It shortened gradually, and died out at last about 8h. 10m. p.m., soon after the sun itself vanished in the haze before reaching the horizon, but without changing the altitude, about 5°, of its base; and it retained to the last the straight, vertical appearance of which many of the vast number of people enjoying the fine evening in the extensive park were admiring watchers. I noticed no horizontal belt of light through the sun, nor mock-suns at their usual distances on its right and left hands, where the bands of cirro-stratus yet extended far enough to have given rise to them if they had consisted of cloud-materials of a fit and suitable description to produce them; and nothing very notable, except the vertical light-beam across the streaky clouds and the sun's intensely red-coloured orb below it, seemed to be of very marked meteorological significance in the beautiful display.

It seems hardly doubtful that the vertical light-beam must proceed in some way from passage of the sun's nearly level rays through horizontal refracting surfaces, such as those, for example, of thin, flat, hexagonal snow-crystals. A natural tendency which such floating crystals and collections of them into flat snow-flakes possess, in fact, of remaining horizontal while falling through perfectly still air, as flat leaves of paper, especially symmetrically shaped ones, if started horizontal on their journeys also may be seen to do,[1] affords fair grounds for an assumption that the sun's slightly sloping rays are really dispersed into these observed vertical light-beams by passing through the horizontal faces of such thin, flat, floating crystals. In what further way the light is spread upwards and downwards in passing through the thin transparent plates seems, indeed, to be a rather more doubtful subject of conjecture; but either want of perfect parallelism of the plates' flat surfaces, perhaps through partial melting, or refractions through the thin plates' bounding faces which give them chisel-edges, supposing these edges to be also slightly rounded off by partial melting, would certainly suffice, in the large proportion of a snow-cloud's floating crystals which optical considerations show must always be suitably oriented to produce refractions of the sun's rays upwards or downwards in directions either vertical or as nearly vertical as possible, to account for the columnar light-beam's well-defined extension in a vertical direction. Yet for better insight into its origin and surer proofs of the correctness of its theoretical explanation, fresh attention to the features and meteorological circumstances of the beam's display when it is well developed would certainly be desirable, and of great value to increase and improve our knowledge of this rather rare and singular form of halo, or occasional form of cloud illumination by the sun and moon. A light north-west wind was blowing on the ground, and the sky seemed to be dimmed by the faint streaks of cirro-stratus only in that quarter of the horizon where the slender beam of yellow light was visible; but the air might easily be quite calm and motionless aloft, in that thinly clouded region of its very high upper strata. A. S. HERSCHEL.

Observatory House, Slough, June 26.

A New Method of using Tuning-forks in Chronographic Measurements.

THE tuning-fork, when used for making time traces in chronographic work, is usually made to vibrate, by bowing with a violin bow, or by percussion, or by rapidly removing a metal block from between the two prongs, or by an electro-magnet the circuit of which is interrupted by the fork itself. When many details have to be attended to in an experiment, the first-mentioned methods are inconvenient, and the last one, namely the electrical, is not without an element of error. In order to obtain the convenience of the electrical method without introducing the error due to the electrical driving of the fork, two forks of the same period are used; the fork which makes the trace is furnished with an electromagnet, but no contact-breaker, the current being controlled by the second fork, which has a contact-breaker. This method of driving a chronographic fork is well known. My new way of using this combination is to cause the chronograph, during the short period during which the records are made, to cut out entirely the electrical circuit from the fork used to make the time trace and to close the circuit again immediately after the records are made. By this means the recording fork is not hampered with a contact-breaker, nor is it subject to the influence due to the electro-magnet, while its trace is being made on the moving surface of the chronograph. After the time trace is made, the circuit is again established, so that the vibration is maintained, and the fork is ready for the next experiment.

Long-tailed Japanese Fowls.

WITH reference to Mr. J. T. Cunningham's letter on these birds in NATURE of June 13, I should like to be allowed to point out that the very interesting evidence he gives is yet not sufficient to prove his point. The words of his correspondent do not necessarily imply that he had personally witnessed the manipulation part of the process adopted to secure extreme length of

[1] This is a rather surprising experiment to those who may have been accustomed, as I have always been used hitherto, to see paper clippings, when tossed up at random, pirouette like little windmills or teetotums in falling through the air. But held by a corner for a moment, out of air-draughts, horizontal, if the hand's support is withdrawn quickly, letting them go at the same time without any impulse, squares, circles, hexagons, or other small cuttings of flat paper will all be found to fall to the ground from any height with very little oscillation, or even sometimes remaining throughout their fall quite horizontal.

feather; and the practices of keeping the birds on perches and of tying up their tails were already known. Such manipulation as is described would be extremely likely to result in the pulling out of the feathers concerned altogether, for all fanciers are well aware that a growing feather is only too easily extracted or knocked out, often to their disappointment.

Moreover, manipulation of the *tail*-feathers, even if it be really practised with the result described, would not account for the likewise abnormal elongation of the saddle-feathers or rump-hackles, or for the fact that the tail-feathers and tail-coverts of the hens of this breed are also slightly elongated, as may be seen in the Natural History Museum specimen.

That a breed of ornamental poultry with the hackles and tail-feathers abnormally elongated could be produced by continual selection of variations in the right direction no breeder would doubt, and so the living specimens of long-tailed fowls one sees in Europe present no special difficulty. Indeed, even the goose, a bird, as Darwin remarked, of singularly inflexible organisation, has produced a breed with abnormally lengthened plumage—the well-known Sebastopol goose.

The difficulty mentioned by Mr. Cunningham, that European specimens of the long-tailed fowls do not approach the length of feather seen in Japanese examples, is undoubtedly a real one. But a simpler explanation than the very unlikely one given by that gentleman would be that the true long-tailed breed is the offspring of a "sport" endowed with more or less continuously-growing feathers, analogous to the rootless teeth occurring in so many mammals, and that the European specimens fail to produce such feathers either on account of a different environment, which is known to have an influence on the growth of feathers, or because they are not good examples of the breed.

It may be objected that continuously-growing feathers are not known to exist in wild birds; but neither do we find in these the duplicated hallux, or the very heavy feathering of the feet, both of which points occur in domestic fowls, and the last in pigeons also.

As to the inheritance of acquired characters, the annals of the poultry fancy furnish no evidence of this, so far as I am aware, nor do they encourage a belief in the theory that the naked head-appendages of the fowl, and its long hackles, are due to stimulation caused by fighting. For the most pugnacious of all breeds, the Aseel of India, has the comb and wattles almost rudimentary, and the hackles, like the rest of the plumage, unusually short and scanty. The same remark applies to the allied Malay or Chittagong breed, while the old English fighting game was hardly modified from the jungle-fowl, and certainly has not a large comb. On the other hand, the large-combed breeds of the Spanish type are not particularly pugilistic, and the size of their head-appendages is recognised by fanciers to be due to selection. So much for the supposed effects of stimulation on living structures.

It may not be irrelevant here to mention a case of manipulation by oriental fanciers which recently came under my notice in India. I had observed some red or chestnut-coloured pigeons with white bars on the wing, and asked my friend Mr. W. Rutledge, who has been a dealer and fancier for nearly half a century, to what breed these birds belonged. He replied that they were of no breed, but that the marking in question was produced by plucking out the feathers constituting the bars three times, when they would be produced white, as I had seen them. But, he added, the birds would not breed young resembling them in this point. I have thought this instance worth recording as illustrating the lengths to which some Eastern bird-fanciers will go, and as showing that experienced men are well aware that acquired characters are not inherited. FRANK FINN.

Decomposition of Copper Oxide.

IN the course of some recent experiments which involved the heating of copper wires in vacuo to temperatures of 1000° or 1050°, several facts were noticed which seem to me worthy of record and of further investigation.

The wires in question were heated in a porcelain tube 12 inches long, the lowest quarter of which was at a uniform temperature, the maximum, while above this the temperature gradually fell off till it reached that of the room.

It was noticed that whenever the vacuum had not been as good as usual the consequent oxidation of the copper in the hot end of the tube did not extend over the whole length of heated wire, but that $\frac{3}{4}$ inch or so of wire was perfectly bright, with considerable oxidation both above and below the bright region.

The temperature of that part of the wire at which brightness occurred was about 950° C. At first sight it appears from this that copper oxide, probably the black variety, decomposes somewhere in the neighbourhood of 950°, but recombines again at a higher temperature.

Another possibility is that the change is connected with the formation of the red oxide, though the appearance of the bright portions of the wires does not favour this idea.

Volatilisation of the metal itself appears to go on at the bright parts, but it is difficult to account for the observed phenomena on an hypothesis of volatilisation alone.

University College, London. PHILIP HARRISON.

The Subjective Lowering of Pitch.

As a question arising out of Mr. Harding's letter (p. 103), it would be interesting to know what is the effect produced by sounding a note loud enough to produce the subjective distortion, while at the same time the note to which it appears to be flattened is sounded more quietly. I suppose discord would be inevitable, but possibly a musical ear would be able to judge whether subjective distortion was prevented in the loud, or produced in the softer, note.

Mr. Allen's argument (p. 182) may, I think, be disposed of in the following manner. He states that the singer should be conscious of flatness. Now if he is singing with an instrument, the note he sings is the only one he can possibly sing without being conscious of discord. If he sings so much higher that his distorted note is depressed till it sounds (in the absence of the instrument) as though it were the correct note, he produces discord with the instrument. His only course is to sing the note of the instrument, reinforce it, and so unconsciously cause the subjective depression of both. I am writing in ignorance of whether the effect is observed in unaccompanied singing and solos on the violin. E. C. SHERWOOD.

St. Peter's College, Westminster.

A Curious Phenomenon.

A CURIOUS phenomenon occurred to some volunteers while on outpost duty on the Delagoa Bay Railway in the Transvaal.

A search-light was fixed up in the station, which was used nightly in scanning the wide stretches of veldt. We were on solitary outpost duty about three miles from the station, and on the still silent nights which are frequently experienced in the clear atmosphere of the high veldt we distinctly heard a low "purring" sound as the ray of light of the station passed over us. As the light approached us one could hear the sound gradually increasing, being loudest as it switched over us and passing away into the nothingness of the silent night. We were too far off the station to hear any vibrations from the mechanism of the search-light, and we all came to the conclusion (being a collection of unscientific men) that the high velocity of the light waves created a sound audible to our ears. On other nights when there was only a slight breeze no noise could be detected.

Can any one of NATURE'S readers tell me if this is a known physiological effect? STANLEY B. HUTT.

Broxbourne, June 20.

THE ANTARCTIC EXPEDITION.

THE instructions to the commander of the National Antarctic Expedition—*verbosa et grandis epistola*—have now been published, together with a similar document, of much greater brevity, addressed to the director of the civilian scientific staff. Most of the former, much even of the latter, would not interest our readers, so we print only a few extracts relating more immediately to the matters recently under discussion. We take first (though not in order) the following clause:—

The *Discovery* is not one of His Majesty's ships, but is registered under the Merchant Shipping Act, 1894, and is governed by it. Copies of this Act will be supplied to you. You will see that the officers and crew sign the ship's articles as required by the Act. The scientific staff will not sign articles, but are to be treated as cabin passengers. You must be careful not to take more than twelve persons as passengers.

So it is now quite clear that the *Discovery* is not on His Majesty's service in any sense of this phrase; the demand also that the members of the civilian staff should sign articles has been dropped as impracticable; so we fail to see why an officer of the Royal Navy without any experience of Polar exploration should have been preferred for the command to a captain in the merchant service familiar with work of this character and less likely to stand upon the dignity of his rank.

We observe also that the civilian director is carefully warned off from interference with all scientific work done by the officers of the ship by the following clause:—

The scientific work of the executive officers of the ship will be under your immediate control, and will include magnetic and meteorological observations, astronomical observations, surveying and charting, and sounding operations.

We may remark that, throughout, the instructions indicate that the framers of them are not quite easy in their minds, for it is solemnly impressed on the commander that he has a grand chance which he must on no account throw away, and advice is given to both which might be put in the homely form, "We hope you will be good boys and not quarrel."

We pass on to the definitions of the objects of the expedition:—

The objects of the expedition are (*a*) to determine, as far as possible, the nature, condition and extent of that portion of the South Polar lands which is included in the scope of your expedition; and (*b*) to make a magnetic survey in the southern regions to the south of the 40th parallel, and to carry on meteorological, oceanographic, geological, biological and physical investigations and researches. Neither of these objects is to be sacrificed to the other.

Geographical discovery and scientific exploration by sea and land should be conducted in two quadrants of the four into which the Antarctic regions are divided for convenience of reference, namely the Victoria and Ross Quadrants. It is desired that the extent of land should be ascertained by following the coast lines, that the depth and nature of the ice-cap should be investigated, as well as the nature of the volcanic region, of the mountain ranges, and especially of any fossiliferous rocks.

Whenever it is possible, while at sea, deep-sea sounding should be taken with serial temperatures, and samples of sea-water at various depths are to be obtained for physical and chemical analysis. Dredging operations are to be carried on as frequently as possible, and all opportunities are to be taken for making biological and geological collections.

Whether the *Discovery* should or should not winter in the ice is left to the discretion of the commander. In that event the following direction is given:—

Your efforts, as regards geographical exploration, should be directed, with the help of depôts, to three objects, namely, an advance into the western mountains, an advance to the south, and the exploration of the volcanic region.

And it is kindly added:—

The director and his staff shall be allowed all facilities for the prosecution of their researches.

In the event of not wintering, the commander is instructed to land a party between Cape Crozier and Cape Johnson, if a suitable place can be found. In regard to magnetic observations special directions are given, from which it appears that the authors of the instructions have taken pains that at any rate this branch of science shall not be neglected.

The instructions to the director of the civilian scientific staff cannot be said to err on the side of precision. For information as to the objects of the expedition they refer him to the instructions given to its commander, which, it is said, will also suffice to indicate his position relatively to the latter. The director can certainly claim to be unfettered as to his methods and objects of work, for there is no direct mention of anything but the disposal of the results. It might, however, have been well for those responsible for these instructions to have indicated the points on which information was especially desired. Still, they have not omitted the precaution of informing the director and members of the civilian staff that they join the expedition at their own risk.

But who is this director? The instructions name two officials, Mr. Hodgson (biologist), Mr. Shackleton (physicist), and the two medical officers, Dr. Koettlitz and Dr. Wilson, who will act respectively as botanist and zoologist when their other duties permit. We are aware that Mr. George Murray will occupy he position of director at the outset of the expedition, but it has been publicly stated that he will not accompany it beyond Australia or New Zealand. Is he to devote himself during his voyage out to training up one of these four in the way that he should afterwards go as his successor, trusting, as with a plant, to quick development under the tropical sun? or is there still a lingering hope of picking up a director somewhere in the Antipodes?—that would indeed be a feat worthy of the *Discovery*!

Magnetic work, as we have said, is happily not neglected. Biological work also, so far as it can be done from the ship, will probably receive attention; how far it will be carried out on land must be left, as we have seen, to the chapter of accidents. Geology has to be content with a bare mention, and the Antarctic ice is just named. Yet a thorough study of its phenomena should have been made prominent among the objects of this expedition. The ice cap of the Antarctic region, as has long been known, is in all probability on a much grander scale than even in Greenland. It is as large as, if not larger than, any which existed in northern latitudes during the glacial epoch. Here, then, if anywhere, information can be obtained as to the work and the indications of such an ice-cap. Certainly these questions will not be solved, nor "the depth and nature of the ice-cap" investigated, by following the coast-line or by anything less than by the researches of a party stationed for a considerable time on the land. But to make information on these questions really valuable it must have been collected by one who is thoroughly familiar with them and can distinguish between trivial and important phenomena. Can we say that any member of the staff possesses these qualifications? Indeed, as we see from the description quoted above, no one of the present staff even claims to be a geologist.

One other point deserves notice. In a covering letter, signed by the chairman of the final committee of the Royal and Geographical Societies, sent with the instructions to their presidents (to which, as it is not marked confidential, we presume we may refer), we find a statement that the instructions have been settled in their present form in consequence of Prof. Gregory's resignation. The reason for bringing in his name is not easy to discover, unless it be that the committee felt ill at ease; for it is a wise policy, when conscious of being in a very questionable position, to hint to all the world that the other party is to blame. Any such innuendo Prof. Gregory can afford to disregard. His actions have been throughout above board and consistent. The Royal Society, as we have already pointed out, has displayed, through its representatives, little care for the interests of science and a lack of moral courage in fighting its battles. We can now only hope for the best; but we fear events will prove that these things also are better managed in Germany than in England.

THE SIMPLON TUNNEL.

FEW undertakings have had to encounter so many difficulties as those which have impeded the construction of the Simplon Tunnel. Apart from the purely mechanical scheme which proposed to cut a narrow space in a definite direction through hard rock for a distance of some 20,000 metres, at a considerable depth below the surface, and the difficulties of a physical character connected with temperature and sanitation, there must be added financial considerations of a very onerous character, possibly increased by the subtle and continuous opposition on the part of existing interests. That all difficulties, save, of course, the actual labour of tunnelling, have gradually disappeared speaks eloquently of the energy and mechanical resource displayed by the engineers, and of the policy and address exhibited by the management. Rumours have appeared now and again in the newspapers of strikes among the workmen and of delays arising from that source; but such inconveniences have always to be anticipated in long-continued workings owing to the gradual changes that occur in the condition of labour. Such annoyances may delay the completion, but they cannot prevent it.

We commented on some of the difficulties and some of the advantages attendant on the construction of the tunnel in a previous article on April 20, 1897, when the project had entered on the stage of a practical undertaking. Four years having passed since that time, it is not uninteresting to review the progress that has been made, and see how far the ingenuity of the engineers has triumphed and what prospect there is of a completion within the term originally assigned. The contract for the construction of the tunnel was signed by Messrs. Brandt, Brandau and Co. on August 13, 1898, but this firm stipulated for three months' grace before boring operations should commence. Consequently, November 13 is the date from which the five and a half years demanded for the construction of the tunnel is to be reckoned, and the critical epoch will be May 13, 1904, when a fine of 5000 francs a day will be demanded from the firm for the non-fulfilment of the contract, or a reward of similar amount be paid to them for the earlier completion. Practically, 2000 days have been assumed as sufficient to bore through 19,734 m. of rock, consequently the average daily progress should be 9·86 m. Of course, this perforation applies to the distance traversed at both ends, because the work really consists in making two tunnels of approximately equal length, whose ends shall join in the middle of the mountain. From data supplied in an article by Herr L. Ernst in *Die Umschau* for April 13, it is easy to compare the actual advance made at either end with the daily average that the contractors hoped to make. The attack on the north side was begun on November 22, 1898, and at first the boring machines encountered a tolerably soft stone, and the progress was proportionately rapid, attaining a daily maximum of 6·5 metres. But on reaching the gneiss, of which the general mass of the mountain is composed, the workmen had to content themselves with a daily average of 5·28 metres. But on January 1, 1901, or 769 days after commencing operations, a tunnel of 4119 metres actually existed, and this gives an average advance of 5·4 metres daily. On the south side, owing to some difficulties with the Italian Government, who objected to the employment of dynamite for blasting operations, the boring machines did not get to work till December 24. Further, a much harder stone had to be penetrated on the southern side, and the daily progress was only 3·71 m.; but the employment of more efficient water power has raised this slow advance to 4·5 m. Effectually, a tunnel of 3148 m. had been bored by January 1; and this gives an average progress of 4·3 m. Clearly, therefore, the daily advance at the two ends is slightly behind the anticipated amount by 0·26 m., but by the removal of initial difficulties and greater experience on the part of the management, this slight deficit may be wiped out.

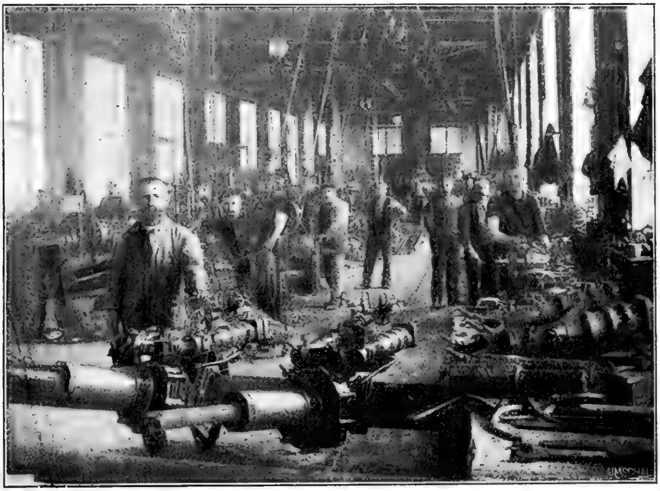

FIG. 1.—Workshop in Brieg, Switzerland, at the foot of the road leading over the Simplon Pass. In the foreground are two boring chisels mounted on one stand. (From *Die Umschau*.)

Very considerable modifications have been introduced in the form and manner of working of the boring machines. In the earlier constructed tunnels the boring chisels, faced with diamond, cut their way into the rock, the motive power being compressed air, the compression being effected by hydraulic machinery. Herr Brandt recognised the loss of mechanical power in this arrangement, and decided to use water pressure direct on the boring apparatus. At the same time he dispensed with the diamond cutting process, which, by means of rapid rotation, worked its way into the stone as a saw, substituting a hard steel face to the chisel, which is driven against the rock and rotates slowly, about six times a minute. The boring tool is made hollow, and the detached fragments collect in the tube and are expelled by water power. Two boring chisels are mounted on each stand and are worked simultaneously (Fig. 1). The aperture of each borer is 10 cm., and is driven into the rock a distance of 2 m. Into the aperture thus formed a cartridge of dynamite is placed and exploded, the rock shattered by blasting has to be removed, and the borer is then pushed forward and the operation continued. On the northern side this cycle of boring, blasting and removal is effected in about seven hours, on the southern side in about an hour less, more time being required to remove the *débris* on the north than on the south. The transport of the masses of rock detached by the blasting is necessarily a work of enormous labour, and compels the boring machine to be idle while it is effected. Herr Brandt designed a machine to accelerate the removal of the rubbish by making it slide along smooth iron plates arranged to receive it. But the application has not proved so useful as was anticipated, and its employment is at present abandoned.

In the explosion of the blasting charge, liquid air or oxygen has been used with good effect. The charcoal covering of the charge is, shortly before use, steeped in liquid oxygen, and the recovery of the gaseous form has the advantage of mitigating some of the evils the presence of carbonic oxide tends to produce. But improvements in this process are still demanded, and experiments are being carried on by Prof. Linde, of Munich, with a view to making the combustion more perfect and removing some of the noxious vapours due to blasting.

We gather that the attempts made to lower the temperature in the cutting have not proved quite as successful as was anticipated. As mentioned in our former article, it was proposed to effect the necessary cooling by the distribution throughout the workings of a water dust under considerable pressure. In pursuance of this plan some 70 litres of water per second, and under a pressure of 100 atmospheres, are scattered throughout the gallery by means of machines placed in the crossway alleys that lead from the main boring to the parallel gallery. Such a liberal expenditure of water has been found sufficient to enable miners to continue working at depths where the ordinary temperature is greater than has been encountered in the Simplon. But Herr Ernst is not yet satisfied; he says that the temperature question is still unsolved, and gives the following figures for comparison with the Gotthard workings.

	Temp. at 7·3 km. from north entrance.	Temp. at 7·05 km. from south entrance.
April and May, 1880 ...	30·46 C. ...	30·53 C.
June, 1882 (after perforation) ...	23·73 C. ...	23·39 C.
July, 1883	22·20 C. ...	23·1 C.

But in the Simplon, at only 1400 metres from the southern entrance, a temperature of 30° C. has been experienced, while the water of a spring near that point showed a temperature of 33° C. Fortunately, the water supply is adequate and easily accessible whether on the north or south side. On the north the Rhone feeds a reservoir formed 44 m. above the tunnel entrance at the rate of 6000–8000 litres per hour. At the southern end, near Isella, the Diveria is equally available, and from both sources it is estimated that the undertaking has at hand the equivalent of 2000 h.p., sufficient for the driving of the pressure-pumps and boring machinery, the ventilation of the shaft, the mechanical workshops, the electric illumination and numerous experimental works.

Recalling the carelessness of life and enervating sickness that decimated the workpeople in the case of the Gotthard tunnel, it is refreshing to notice the care and attention that are bestowed on the comforts of the operators in this instance. Provision is made for frequent baths, and changes of clothes are insisted upon, the maintenance of a simple system ensuring regularity and obedience. A school and hospital, not to mention a theatre, are provided for the use of the workpeople, and hostelries are erected wherein the meals are arranged at fixed and certainly very low prices. A regular meal of soup, meat and vegetables costs but ·50 cents, the full ration for the day being 1·10 francs. The daily wage does not seem large at 3 or 4 francs, but apparently is sufficiently attractive, and we are assured that the careful wage earner can send a modest contribution to his relatives every month. A whole colony has settled down under the shadow of the Simplon, but the man whose genius has called into being this hive of workers, whose activity has encouraged and animated the whole undertaking, whose resourceful energy has overborne so many difficulties, is no longer at the fore to guard against future dangers and to guide the whole to a successful issue. Herr Brandt died in November 1899, when progress was slow but assured. He has, however, left four able lieutenants, who, trained in his school and possessed of not less devotion and energy, will carry through the arduous work and permit us to see yet another and the longest tunnel under the Alps pushed to a successful termination.

NOTES.

PROF. E. VAN BENEDEN, professor of zoology and comparative anatomy in the University of Liège, has been elected a correspondant of the Paris Academy of Sciences in succession to the late Sir William Flower.

THE next meeting of the American Association for the Advancement of Science will be held in Denver, Colorado, on August 24–31. The membership of the Association is now larger than it ever was before, more than eight hundred new members having been elected within the past year. As already mentioned, it is proposed to hold a winter meeting each year in the week in which New Year's day falls, and the summer meeting may eventually be omitted altogether. Of the fourteen universities forming the Association of American Universities, twelve already do not open their terms until after the week in which New Year's day occurs, or have arranged not to do so, and it is expected that the remaining two will come to the same decision. A convocation week will thus be set aside for the annual meetings of scientific and learned societies, and the difficulty of getting men of science together during the summer holidays will be avoided.

A NEW magnetic observatory is being established just now in France. It is situated at a distance of only thirty miles from Parc St. Maur, where records have been rendered impossible, electrical railways using the earth for return currents having been laid in almost every direction. The new observatory is situated in the small parish of Villepreux, in] a district occupied by farms, cornfields and woods. The authorisation was granted by the Government only when the railway companies had paid to the National Treasury a sum of 1200*l*., sufficient for paying all the expenses of the new building. These have been greatly diminished because the land covers about ten acres belonging to the Government, and some old buildings without any artistic value can be demolished for procuring the stones required in order to construct the magnetic pavilions and a house for the observer. M. Moureau will continue to reside at Parc St. Maur, and the new observatory will be considered as an accessory to the old one.

THE importance of the scientific study of Africa and its native inhabitants has often been urged in these columns. We notice, therefore, with much satisfaction that the African Society has been formed with the object of enlarging and extending the work done by the late Miss Mary Kingsley, so s to include the whole of Africa in the field of operations. The Society will thus not only commemorate the name and continue the investigations of Miss Kingsley, but should lead to the organised investigation of the native races of Africa, the natural history, resources, diseases and other subjects upon which exact knowledge is required. In Germany the publication of a journal, as well as of some books dealing with many of these subjects, has already been inaugurated under the auspices of the Government. In France an independent society, more on the lines of what is now proposed, is at work in French Africa, and other European nations are advancing in the same direction. England ought not to be behind in this work, and the new society will do good service by encouraging interest in its objects. At the meeting held on Friday last, when the first meeting of the Society was held, the Marquis of Ripon, who occupied the chair as president, pointed out the need for scientific research in Africa. In order to discharge the responsibilities of Empire it is essential, he remarked, to set to work to understand the full and complete nature of the problems with which we had to deal, to study the whole field of African affairs, and, above all, to endeavour to understand, so far as might be possible, the thoughts, the views, the opinions and laws of the people. It is only by this means that we can arrive at a state of things in which our administration is likely to be successful. The secretary of the Society is Mr. R. Sewell, 22, Albemarle Street, London, W., to which address all communications should be sent.

THERE is no doubt that the establishment of an experimental tank in which models of ships could be tested for resistance, form, stability and other qualities would benefit the science of naval architecture in this country. The subject was brought before the meeting of the Institution of Naval Architects at Glasgow last week, and received much support. Dr. Elgar directed attention to this question in describing how the Government tank at Washington was available for the use of private shipbuilders on the payment of a fee merely covering expenses. Mr. A. F. Yarrow, referring to this statement, pointed out that the British Admiralty had an experimental tank of their own at Haslar, near Portsmouth. There was one other tank in this country, which was owned by a private shipbuilding firm. Mr. Yarrow submitted that, having in view the rapid increase in competition in shipbuilding, it was desirable that no stone should be left unturned by the shipbuilders in this country to keep well to the front, and that all the means modern knowledge could give should be made available for ship designers. He therefore proposed that the Institution of Naval Architects should take into consideration whether such a tank should not be established under its auspices, so that it might be available, not only for shipbuilders in this country and members of the Institution, but also for all willing to pay for the information to be obtained, irrespective of nationality. Sir Nathaniel Barnaby referred to the immense benefit that had accrued to the science and practice of naval architecture by the investigations of the late Mr. Froude, which he had carried out by means of the experimental tank he ad originated, and by means of which various qualities of different forms of ship could be determined with models of practicable size. At the present time all types of British war vessels were tried in this way. The resolution suggested by Mr. Yarrow was to the following effect:—"That this meeting, having regard to the desirability of establishing a tank in this country for testing the resistance of models, and which might be available for all shipbuilders, request the council of the Institution to take the matter into serious consideration with a view to arriving at the best means of carrying out the suggestion." This was put as a motion by Lord Brassey and seconded by Sir Nathaniel Barnaby, and carried with acclamation.

DURING the past few days exceptionally high temperature conditions have prevailed in New York and the neighbourhood, and have resulted in numerous deaths from heat apoplexy. On Monday shade temperatures from 103° Fahr. to 111° Fahr. were recorded, and the official reading was 98° Fahr. The minimum night temperature was 87° Fahr.

THE Berlin correspondent of the *Times* announces the death of Prof. Johannes Lamp, one of the scientific members of the expedition which was charged with the demarcation of the boundary between German East Africa and the Congo State in the neighbourhood of Lake Kivu. Prof. Lamp, who was born at Kiel, was for some time employed at the Geodetic Institute in Berlin. He was afterwards appointed to the observatory at Kiel, and held a professorship at the University of that city.

WE learn from the *British Medical Journal* that a bust of Dr. Armauer Hansen, the discoverer of the bacillus of leprosy, will be unveiled with appropriate rites in the Lungegaards-Hospital at Bergen on August 10. In order to give the ceremony as much of an international character as possible, an invitation has been issued to prominent members of the medical profession throughout the world by Prof. Rudolf Virchow, president of the committee. Gerhard Henrik Armauer Hansen was born at Bergen in Norway in 1841, and has spent the whole of his professional life in that town, where he was for many years on the staff of the Lungegaards-Hospital.

IT is stated by the *Engineer* that the General Electric Company of Berlin has just completed near Naples, in the valley of Pompeii, an installation for the transmission of electric energy, all the conductors used being of aluminium. This installation comprises three horizontal turbines of 150 horse-power, working at 190 revolutions per minute. These turbines each drive a tri-phase alternator, and the current, at a tension of 3600 volts, is led along three aluminium lines to Pompeii, Sarno and Torre Annunziata. The first of these lines, which has a length of about 3 kilometres, leads to a substation comprised of two three-phase transformers of 45 kilowatts. The second line, which leads to Sarno, has a length of 15 kilometres; it conducts the current to a tri-phase motor working at 3500 volts, and driving a continuous-current dynamo of 36 kilowatts capacity. This installation supplies a three-wire system at a tension of 240 volts. Finally, the line to Torre Annunziata has a length of 3·5 kilometres, the current serving for motive power in the macaroni factories in the district.

IN an interesting and useful supplement to the Daily Weather Report, the Meteorological Council have published values for pressure, temperature, rainfall and bright sunshine for each month of the year. The sunshine values refer to a period of twenty years, temperature and pressure thirty years, and rainfall thirty-five years, all ending with the year 1900. With regard to temperature, a glance at the tables shows when the highest maxima of the period occurred. The maxima in London were: 96° (August 1876), 91° (June 1878), 95° (July 1881), and 91° (September 1898). The coldest winters occurred in 1881 and 1895, the lowest readings in London being respectively 9° (January) and 10° (February). Much lower readings were registered in other parts of England and in Scotland.

WE have received the Report of the director of the Liverpool Observatory, Bidston, containing the result of the astronomical and meteorological observations taken in the year 1900. The work of this Observatory dates back to the year 1845, and the observations, which are taken with every care, form a very valuable contribution to our knowledge of those sciences. The transit instrument has been used continuously for the determination of time and continues to give entire satisfaction, and the self-recording meteorological instruments have worked without failure the whole of the year. A Milne seismometer, provided by the Earthquake Committee of the British Association, has recently been added to the existing apparatus. As in former years, a useful comparison has been made between the records of Osler's and Dines' anemometers, and the results for each day tabulated. During a very severe gale on December 28, 1900, the Osler instrument recorded a pressure of 44·4 pounds on the square foot, the resulting maximum velocity shown by the Dines' anemometer being eighty-two miles.

M. ARÇTOWSKI, of the *Belgica* Expedition, contributes to *Ciel et Terre* a note on the climate of glacial periods. Assuming the changes in the level of the snow-line to have been due to changes of temperature only, M. Arçtowski compares its present position at Cape Horn and in South Georgia, and estimates the corresponding differences of mean temperature, obtaining for a difference of level of 800 to 900 metres a difference of temperature of about 8° C. He urges the special importance of studying the conditions in oceanic climates, and expresses the opinion that the exploration of the Antarctic regions will give the true explanation of the occurrence of glacial periods.

WE have received from the authors a reprint of a paper published in the *Memoires* of the Belgian Academy of Sciences, by MM. H. Arçtowski and A. F. Renard, on the soundings and bottom deposits obtained during the expedition of the *Belgica*. Although this is a preliminary report, it is not expected that the detailed examination of the deposits, which remains to be completed, will seriously modify the conclusions arrived at. The most important points disclosed by the soundings are the existence of a depression of 4040 metres to the south of Staten Island, and of a continental plateau extending south of the 70th parallel. It is noteworthy that the boundary of this plateau is indicated by the isobath of 500 metres rather than by the usual 200 metres. In examining the deposits, the methods employed by Thoulet have been employed in preference to those of Murray and Renard, as the samples are chiefly terrigenous. The chief interest lies in the obvious iceberg origin of most of the deposits, indicating the presence of glaciers on continental land to the south and east of the region of the *Belgica's* drift. Another feature is the interruption of the zone of diatom ooze in this region.

AN account of the first voyage of the Norwegian fishery steamer, *Michael Sars*, during the summer of 1900, by Prof. Hjort, is published in the last two numbers of *Petermann's Mitteilungen*. The paper consists of three distinct parts—(1) oceanographical results, by Bjorn Helland-Hausen; (2) the distribution of some of the chief forms of Plankton in the Norwegian Sea, by Dr. H. H. Gran; and (3) fishery investigations, by Dr. Hjort. The course of the expedition was from Bergen, across to Iceland, along its north coast to Denmark Strait, thence to Jan Mayen, the Lafotens, Porsanger Fjord, Bear Island, westward to near long. 10° E., and home. The cruise lasted from July to September, and these preliminary results afford important extension and confirmation of the work of the Danish *Ingolf* expedition in the same regions.

THE July Pilot Chart for the North Atlantic and Mediterranean, issued by the Meteorological Office, shows graphically the general circulation of the air and of the sea for the month. The region in which gales form as much as 10 per cent. of the wind observations is now limited to the immediate neighbourhood of the southern extremity of Greenland. With the month of July the conditions in the tropics begin to assume a more disturbed appearance, and the seaman consequently finds the letterpress to be largely devoted to a description of West Indian hurricanes and a concise summary of practical rules for handling ships in or near these storms. The path of one of the hurricanes of July 1837 is shown on the chart. As only 355 hurricanes have been recorded in 300 years, the annual average is little more than one, but in July 33 were experienced last century, so that one may be expected every three years in this month. A good deal of information is given on the winds in the Dardanelles. An inset chart gives a thunderstorm type of pressure distribution over western Europe, the remarks stating that there are three distinct classes, (1) those coming from the southward; (2) those forming locally; and (3) those appearing as secondaries to depressions in the north. The first of these is the one illustrated. It is interesting to observe how the shading representing fog has been expanding month by month, until in July it extends without a break right across the Atlantic between 40° and 50° N., but it is only about the middle of the Bank of Newfoundland that the frequency amounts to 50 per cent. Mariners going up the Labrador coast are informed that during the few days of summer the displacement of the horizon by mirage in this neighbourhood occasions great difficulty in obtaining good observations for position. The north-eastward extension of the Gulf Stream drift towards our coasts, which was shown to be interrupted in May and re-established in June, is again overcome by a general southward flow of the surface water between 10° and 30° W., the Gulf Stream water apparently not extending northward of the 50th parallel even on the western side of the ocean. Icebergs have at last appeared about the banks, a number having been sighted between April 30 and June 1, nearly all clustering about 48° N. 48° W., but one in 46° N. 56° W.

WE drew attention in NATURE (January 17) to the first number of the *Geologisches Centralblatt*, which is edited by Prof. Dr. K. Keilhack. We have since received Nos. 2 to 10, the last named published on May 15. The total number of works dealt with is 1027, so that our estimate that about 2500 will be recorded in the year is probably correct. It is hardly possible to judge of the completeness of the record until the volume for the year is published, but we think that space could be saved by shorter notices of works that are not original articles, such as excursion notes, popular general papers on geology and economic products, text-books, &c. As an illustration of somewhat unequal treatment we observe that the notice of the Summary of Progress of the Geological Survey of the United Kingdom occupies two pages, and that of the Summary Report of the Geological Survey of Canada only five lines. A valuable feature in the work is the insertion of tables showing new groupings of strata and revised classifications of organic remains. Taken as a whole, it cannot fail to be of permanent service to geologists.

THE University of Nebraska publishes a contribution (No. 5) to the Botanical Survey of Nebraska, conducted by the botanical seminar. The present instalment consists of a number of papers on the general features of the flora rather than of lists of species.

IN the *Journal* of the Royal Microscopical Society for April and June are two of Mr. E. M. Nelson's useful papers on the construction of the microscope—on tube length and on the working aperture. Mr. Nelson points out that there are no less than three different measurements known as tube lengths, viz. the mechanical tube, the natural optical tube length, and the conventional optical tube length. A table is given of the variations in the lengths of the two different optical tubes for the objectives of various makers and the effect these variations have upon the power. In the second paper Mr. Nelson advocates the importance of distinguishing more accurately than has hitherto been the practice the precise ratio of the diameter of that part of the objective which is utilised to the diameter of the lens itself.

THE report of the experiments superintended by the Department of Agriculture in Cambridge University has just been issued. The experiments are conducted on various farms in the adjoining counties, which contribute towards the expenses of the Agricultural Department at the University. The volume issued is really a bundle of reports written by different persons, and no attempt is made to describe the work as a whole. Most of the experiments are of considerable interest, and will be of practical value in their respective localities. More exact descriptions of the conditions of each experiment are, however, required if any real addition to our knowledge is intended. An analysis of a soil conveys no certain information unless we know the depth which the sample represents. We cannot interpret the variable action of manures unless we know the rainfall during the seasons in question.

IN part iv. of vol. xxii. of the *Notes* from the Leyden Museum, Dr. O. Finsch catalogues the birds of the "South-west Islands," with three coloured plates of some of the less known species. The small islands in question form a chain stretching from the northern extremity of Timor in an easterly direction to Timorlaut. Although the birds from some of these islets have been described by the officials of the Tring Museum, of others the bird-fauna is practically unknown. Dr. Finsch records a total of 123 species. One of the most striking and beautiful of these is the great red-brown fruit-pigeon named by Schlegel in honour of Dr. Hoedt, a former worker on the avifauna of these islands. For the future, the author suggests that this bird should represent a genus by itself, and be known as *Alopecaenus hoedti*.

THE number of new generic, specific and subspecific names that have been proposed for North American mammals during the last twenty years is so enormous that it was a matter of the greatest difficulty for a student to be certain that he had exhausted the list in any particular group upon which he might be engaged. This difficulty has been removed by the appearance of a "Synopsis of the Mammals of North America and the Adjacent Seas," by Dr. D. G. Elliot, which forms vol. ii. of the zoological series of publications of the Field Columbian Museum. The synopsis is well illustrated by reproductions from photographs of skulls. Although the author states that many of the species and subspecies recorded are probably nominal, the task of abolishing such superfluous names is left to his successors. In the main the work appears to be very accurate, but we notice a few omissions, and when describing the wood-bison the author states that it is a larger animal than its cousin of the plains, although the measurements given of the two forms indicate just the contrary.

IN the issue of *Die Umschau* of June 15, Prof. W. Amalitzky announces the discovery of gigantic anomodont and other reptiles in a Permian deposit at Sokolki, on the Dwina, Russia. The bones occur in an old river channel cut in Lower Permian beds and subsequently filled up with sandstone. Regular excavations have been undertaken, with the result that a very large number of skeletons and separate bones have been disinterred. Most of these are embedded in hard nodules, and a considerable sum of money is required for their proper development. Most noticeable is the discovery of no less than from fifteen to twenty skeletons of the huge anomodont Pariasaurus, hitherto known only from South Africa. One of these has been developed, and measures 11 feet in length. Remains of Dicynodon and other anomodonts, as well as dinosaurs and a labyrinthodont, are likewise recorded. According to Prof. Amalitzky, the reptilian remains are associated with ferns belonging to the well-known "Glossopteris flora"; and it would accordingly appear that this peculiar southern fauna and flora, which formed a belt round the globe in low latitudes during early Mesozoic times, had a northern extension into eastern Europe.

THE *American Museum Journal* for April and May contains a figure of one of five specimens of the Greenland musk-ox which have recently been mounted for exhibition. This form of musk-ox, it will be remembered, was described not long ago in NATURE as *Ovibos moschatus wardi*; and the American Museum has now acquired a fine series of specimens, which have enabled Dr. J. A. Allen to point out characters regarded as sufficient to justify the assignation of specific rank to this animal. On a later page of the same journal, stress is laid on the importance of exhibiting in museums groups of mounted mammals and birds amid their natural surroundings, as it is by this means alone that their full educational value can be obtained from the specimens. By the aid of liberal donations from private sources, much has already been done in this way in the American Museum, and it is confidently hoped that still more will be accomplished in the near future. It is a matter for regret that, so far as the larger mammals are concerned, little or nothing of this sort has hitherto been attempted in our own national collection. But millionaires in this country do not seem inclined to devote some of their spare thousands to such objects.

AN address on the historical development and the problems of anthropology, delivered by Dr. B. Hagen at the anniversary gathering of the Senckenberg Society of Natural Science, Frankfort on the Main, last year, has been translated by Mr. W. L. H. Duckworth and published by the Anthropological Laboratory, Cambridge. According to the translation, which alone has reached us, Dr. Hagen adopts a common but somewhat arbitrary division of the science of man into "anthropology," which deals with the physical structure of man and "the mode of life," and into "ethnology," or psychical aspect, comprising folk-lore, comparative psychology, sociology and psycho-physics. It is not clear what "the mode of life" means or why that is regarded as physical and the investigation of the senses and sense organ entirely relegated to "ethnology." Speaking of craniology, Dr. Hagen states that "we are not at the present day in a position to determine with certainty the racial identity of a given skull, with the exception, perhaps, of hyper-typical examples of Australians or Negroes." He believes there is but a single cranial type, the mesocephalic, of whose varieties the dolichocephals and brachycephals are the opposite extremes. "Stature is also a dangerous pitfall for metrical anthropology in general." Evidently the "anthropologists" of this classification cannot reduce the facts of the study of man into order without the help of the "ethnologists;" but we are warned that "the linguist must not regard the ethnologist, nor he in turn the anthropologist, with disdain."

CATALASE is the name given to a new enzyme of general occurrence described by Dr. Oscar Loew in Report (No. 68) of the U.S. Department of Agriculture (Division of Vegetable Physiology and Pathology) with special reference to the tobacco plant. This enzyme possesses the power of producing catalytic decomposition of hydrogen peroxide, a decomposition which, according to the author's experiments, is probably not produced by any other known enzyme. The enzyme appears to exist in an insoluble and in a soluble form, which are designated α- and β-catalase respectively. The former is probably a compound of the soluble catalase with a nucleo-proteid, while the β- form is an albuminose and can be liberated by the action of very dilute alkaline media upon the insoluble catalase. The behaviour of the enzyme towards various salts, acids, bases and other reagents has been carefully investigated. Experiments on the nature of catalase indicate that it is an oxidising enzyme, the most characteristic reaction studied in this direction being its rapid oxidation of hydroquinone to quinone. Numerous tests have established the general occurrence of catalase in the vegetable kingdon. No living plant or vegetable organ tested was found free from it, some plants containing more of the soluble, others more of the insoluble, form. In the animal kingdom it also appears to be widely distributed, having been found in aqueous extracts of spleen, pancreas, liver, kidney, brain, muscles and blood serum. Infusoria, insects, worms and molluscs were also examined, with positive results.

THE additions to the Zoological Society's Gardens during the past week include two North African Jackals (*Canis anthus*) from Algeria, presented by Mr. G. E. Hope; a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mrs. Mould; a Suricate (*Suricata tetradactyla*) from South Africa, presented by Captain R. Feilden; a Leopard (*Felis pardus*) from Africa, presented by Captain G. Burrows; two Stanley Cranes (*Anthropoides paradisea*) from South Africa, presented by Mr. A. W. Guthrie; a Yellow-cheeked Amazon (*Chrysotis autumnalis*) from Honduras, presented by Mrs. Bullock; a Rough-legged Buzzard (*Archibuteo lagopus*) from Norway, presented by Dr. E. A. Williams; a Leopard Tortoise (*Testudo pardalis*) from South Africa, presented by Major J. Day; five Leith's Tortoises (*Testudo leithi*), eight Basilisk Chameleons (*Chamaeleon basiliscus*), two Common Chameleons (*Chamaeleon vulgaris*), three Schneider's Skinks (*Eumeces schneideri*) from Egypt, presented by Mr. Stanley S. Flower; a Spix's Macaw (*Cyanopsittacus spixi*) from North Brazil, two Barbary Wild Sheep (*Ovis tragelaphus*) from North Africa, a West African Python (*Python sebae*) from West Africa, fourteen North American Trionyx (*Trionyx ferox*), six Lesueur's Terrapins (*Malacoclemmys lesueuri*) from North America, seven Roofed Terrapins (*Kachuga tectum*) from India, two South American Rat Snakes (*Spilotes pullatus*) from South America, three Cunningham's Skinks (*Egernia cunninghami*) from Australia, two Wallace's Lories (*Eos wallacei*) from Waigiou, a New Zealand Parrakeet (*Cyanorhamphus novae-zealandiae*) from New Zealand, deposited; two Spoonbills (*Platalea leucorodia*), European, purchased; a Burrhel Wild Sheep (*Ovis burrhel*), a Squirrel-like Phalanger (*Petaurus sciureus*), two White Ibises (*Eudocimus albus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

SPECTRUM OF NOVA PERSEI.—In the current issue of *Comptes rendus* (vol. cxxxii. pp. 1542-1544) M. Deslandres gives a third series of observations of the spectrum of Nova Persei as obtained at the Meudon Observatory. Since the previous communication, spectrographs of varying power have been installed for use with the two telescopes of 0·84 metre and 0·60 metre aperture, and both photographic and visual records of the spectrum obtained during the periods of minima, although unfavourable weather has considerably interfered with their continuity. In this later work special attention has been devoted to the expected detection of the principal nebular lines. M. Deslandres states that during the first stages the principal green lines present were distinctly not the nebular lines, but the lines of parhelium, λ492 and λ5015, this being well shown in a photograph taken on March 3. On a plate taken on April 17, however, the measured position of the chief green line was λ5008, but on account of breadth of line the value is of course only approximate. The star was near its minimum brightness on this date. The gradual varying intensity of this line relative to the H_β line of hydrogen is then described, the details being in close agreement with those already published by other observers.

On May 14 a fainter line was seen near the next nebular line, about λ4959, the star being less than 7th magnitude, and he concludes that at that time the spectrum of the Nova was completely nebular, also mentioning that M. de Gothard had detected the ultra-violet nebular line λ386 in the spectrum of the star.

DARK SPOT ON JUPITER.—In the *Astronomische Nachrichten* (No. 3724) Mr. T. E. R. Phillips gives the results of several observations by others and himself extending from March 2 to June 2.

The spot as seen by these observers is in the white north tropical zone, in about latitude +15°. At present it appears to be quite detached from the northern edge of the north equatorial belt, but when first seen gave the impression of being merely a dark projection from that belt into the north tropical zone. Possibly the reason for the present appearance is the apparent narrowing of the belt which has been observed for some time past.

A table is given showing the results of nine determinations, the discussion of which indicates a period of 9h. 55m. 29·7s.

THE METEORIC EPOCH OF JULY AND AUGUST.

METEORS are generally rare in the early part of the year, and, in May and June, twilight is so strong that it obliterates faint objects and leaves only the more conspicuous class of meteors observable. But in July, though the sky is still very light and the nights extremely short, these objects become fairly plentiful and particularly so during the last week of the month, when the horary rate of apparition is about three times as great as it is on ordinary nights of spring and midsummer. The meteoric observer regards July and August not only as one of the most productive seasons of work, but one which in the interesting character of its results will compare favourably with that of any other epoch of the year.

There is a rich shower of Aquarids annually visible on about July 27-31, and apart from this stream the great system of Perseids, which has rendered the month of August so famous in meteoric annals, has actively commenced and supplies no inconsiderable proportion of the shooting stars visible at the close of July. Other showers are plentifully distributed over the firmament, but the majority are very feeble and may only be distinguished by close and prolonged watching during several clear nights.

The writer recently undertook the rediscussion of about 260 meteors which he has recorded from the shower of Aquarids, in various years, with a view to discover whether there were any indications of motion in the radiant. Grouping the observations into short periods and deducing the place of the radiant for each of them, it was found that no displacements occurred other than those which might be fairly attributed to errors in registering the paths. The radiants came out as follow:—

	α °	δ °	
July 23-25 ...	... 335	− 11	11 meteors
July 26-31 ...	.. 338	− 12	190 ,,
August 1-5 ...	... 337	− 12	18 ,,
August 6-13 ...	... 335	− 11	12 ,,
August 14, 1887	... 335	− 10	5 ,,
August 18-25 ...	... 339	− 11	20 ,,

The centre of radiation, like that of the October Orionids, appears, therefore, to be motionless, and it continues visible for more than a month. In observing this stream care must be taken not to confuse it with two other pretty rich and contemporary showers at 345° ± 0° and 339° − 30°. The latter is near the bright southern star Fomalhaut.

In this department the observer's efforts have to be regulated in a great measure by moonlight, and this year our satellite will interfere in the earlier and later part of July. But it is probable that, with suitable weather, the first indications of the Perseid display may be well observed on about July 11-15. As the radiant centre of this system travels E.N.E. with the time, the observer should keep his materials for each night separate, and determine the place of radiation on every date when the conformable paths are adequate for that purpose. This position can scarcely be defined, either with safety or accuracy, when less than five well-observed meteors have been registered from it. But it is often satisfactorily obtained when two observers at separate stations record the same meteor. In a case like this the evidence is conclusive as to the position of the radiant, though it may be rendered a little inexact by errors of observation. But in instances where meteors are seen at one place only there are possibilities of mistake in attributing the radiants, for these have necessarily to be assumed from the directions of flight and visible aspect of the objects observed. In the case of the Perseid shower there is not, however, much probability that serious errors will occur in this respect, but everything depends upon the discrimination and discretion of the observer.

In recent years many amateurs have participated in systematic observations of the Perseids, and the number of doubly observed meteors has been greatly augmented. In July, 1900, three early Perseids were recorded in duplicate and gave heights and radiants as follow :—

	Height at beginning. Miles.	Height at end. Miles.	Radiant. ° °
July 19	81 ...	54 ...	17+50
,, 23	84 ...	55 ...	24+52
,, 30	95 ...	50 ...	30+52

In time it will be possible to accumulate a sufficient number of these observations to assign the radiant on every night during the last half of July. There will certainly be small errors in the individual positions, and they will not absolutely agree in showing the regular progression of the radiant eastwards, but the mean places derived from a considerable number of meteors will no doubt yield very satisfactory results.

In previous years much has been effected at the July and August epoch, but still more remains to be done. Photography, of which so much was expected, has achieved little, but its possibilities are great and it may ultimately prove as successful in this department as it has done in several others. The fact, however, remains that we are still mainly dependent upon eye observations, though they are no more than rough and hurried estimates of position, and scarcely capable of being usefully employed in any refined or critical investigations of the subject. But with care and long practice it is possible to acquire a degree of accuracy which would hardly have been credited, and we must not forget that some important conclusions have been safely based on rough eye observations. The virtual identity of comets and meteors has been established, the heights and velocities of meteors approximately determined, while the positions of some hundreds of radiants have been ascertained with fair accuracy. Features such as the motion of the Perseid centre, the stationary aspect of the Orionid and certain other radiants, and the large area of radiation of the meteors of Biela's comet, have been demonstrated. But much additional data are required, and as photography has hitherto supplied very meagre results, observers have to fall back upon the old-time method as vastly more productive if far less precise. It will be remembered that some years ago it was thought that the photographic plate would soon supersede the observer in regard to the delineation of planetary detail, but this idea has not been realised. It is true that planetary and meteoric observations are different and therefore not strictly comparable, but we have gained enough experience to see that the meteoric observer is in no immediate danger of being displaced. W. F. DENNING.

THE "EDISON" STORAGE CELL.

CONSIDERABLE interest was aroused a short time ago by the announcement that Mr. Edison had invented a new secondary battery. As was only to be expected of a rumour, circulated mainly by the lay Press and dealing with one of Mr. Edison's inventions, it was said that the new cell was going to revolutionise entirely the electrical storage of energy and to throw open to the undisputed control of the electrical engineer the much-desired field of motor-car work. Fortunately, in this case, even if rumour has been somewhat extravagant, it has not been without foundation. Mr. Edison has in reality invented a new storage cell which is novel in principle and full of promise. A full description of the invention was given by Dr. A. E. Kennelly at the annual meeting of the American Institute of Electrical Engineers on May 21, and we are able, from a reprint of this paper which appeared in the *Electrical Review* of New York (May 25), to obtain data for a preliminary consideration of the merits of the cell.

Mr. Edison—like many other inventors, only with more success than is met with by most—set out with the object of devising a cell which should possess the following merits :—(1) Absence of deterioration by work, (2) large storage capacity per unit of mass, (3) capability of being rapidly charged and discharged, (4) ability to withstand careless treatment, and (5) inexpensiveness.

It will be best first to describe the solution that Mr. Edison has offered, and then to examine, as far as is possible from the information available, to how great a degree the above requirements are satisfied. The problem thus clearly stated by Dr. Kennelly is one which has been long realised by all interested in the matter, and by none, perhaps, more than by the makers and users of motor-cars. The one great difficulty in the construction of a good electrical motor-car, or in the equipment of a satisfactory system of accumulator tramways, has been the want of a suitable storage cell. If this were only provided, we have been told, then the electrical motor-car would know no rival, seeing that it would be free from all the objectionable noise and smell incidental to petroleum automobiles. It is, therefore, most earnestly to be hoped that the new Edison cell will do all that is claimed for it.

The cell is an entirely new departure in storage batteries, the materials used in its construction being iron and nickel oxide. The active material of the negative plate of the cell consists of iron, that of the positive plate of a superoxide of nickel believed to have the formula NiO_2. Thus the iron corresponds to the spongy lead and the oxide of nickel to the lead peroxide of a lead accumulator. The electrolyte used is an aqueous solution containing about 20 per cent. by weight of caustic potash. The E.M.F. of this combination—iron, potassium hydrate, nickel superoxide—is about 1·5 volts when fully charged and falls to about 1·15 at the end of the useful discharge. At the end of the discharge the iron is oxidised and the nickel oxide reduced ; the charging process carries back the oxygen through the potash solution from the iron to the nickel plate, the energy being thus stored in the reduced iron, which, though unaffected by the solution in ordinary circumstances, is reoxidised when the cell is allowed to discharge. The solution, therefore, does

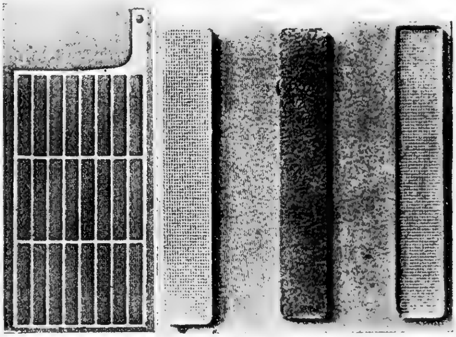

FIG. 1.—Grids and Briquettes, Edison Storage Battery. (From *The Electro-Chemist and Metallurgist.*)

not apparently enter at all into the chemical action which takes place, but only serves as a vehicle for transporting oxygen from the one plate to the other ; this is of considerable advantage, as it allows a minimum of solution to be employed.

The mechanical construction of the two plates is identical, the only difference between them being in the active material used. The plates are made of comparatively thin sheets of steel (a little more than 0·5 mm. thick), out of which rectangular holes or "windows" are stamped. In the plates exhibited there were three rows of eight such windows, these holes occupying, of course, by far the greater proportion of the area, the steel framework being merely sufficient for strength and rigidity. Into these holes are fitted small nickel-plated steel boxes containing the active material in the form of closely consolidated briquettes. These boxes are somewhat thicker than the grid, being about 2·5 mm. thick in the finished plate, and are perforated, back and front, with numerous small holes to allow access of the electrolyte to the active material. The general appearance of the grid and briquettes can be seen from Fig. 1.

The positive briquettes are made by mixing a finely divided compound of iron with a nearly equal volume of thin flakes of graphite, the graphite being added to increase the conductivity of the briquettes. The mixture is pressed in a mould under an hydraulic pressure of about two tons per square inch. The surface area of each face of the briquette is about 3 inches by ½ inch. The negative briquettes are made in a precisely similar way, only a compound of nickel is used in place of the compound of iron. The method by which these compounds are obtained and their constitution was not described in Dr. Kennelly's paper, but from the patent specification it appears that the compound of iron used is the monosulphide, FeS, which is formed after being made up into the briquettes by electrolytic oxidation in a solution of potassium hydroxide. The superoxide of nickel is prepared in the same manner by electrolytic oxidation of the ordinary hydrated oxide of the metal. Cobalt, it is said, can be used instead, but is more expensive. The briquettes of active material are placed in the little nickel-plated steel boxes, a cover is put on, and the boxes are then inserted in the "windows" of the grid. The assembled plate is then subjected in an hydraulic press to a pressure of about 100 tons (about 1 or 1½ tons per square inch), thus tightly closing the boxes and, by bending their sides over the edges of the recesses in the grid, fixing them firmly in position and making the whole into a rigid plate. The plates are separated, positive from negative, by thin perforated sheets of hard rubber, and are placed in a steel box which is filled up with the potash solution. The cell is then charged by passing current through it from the nickel to the iron plate, thus oxidising the nickel compound to superoxide of nickel and reducing the iron compound to spongy metallic iron.

It is obviously impossible to say at present how far this cell will satisfy the five conditions already stated. With regard to the first and the last, for example, no data are as yet available. The first is naturally one of the most important considerations, since it is necessary not merely that the cell should have a long life, but that it should not deteriorate too much even when subjected to somewhat careless treatment, as it is certain to be if it come into at all general use for motor-cars. Certain experiments which were quoted by Dr. Kennelly lead, however, to the hope that the cell will not be found wanting in this respect. Thus it was stated that the battery would stand without injury, not only being completely run down, but even being afterwards charged in the wrong direction. Mr. Edison also states that the nickel plate can be removed from the cell and dried in the air for a week without being injured, and if charged when thus removed will not appreciably lose its charge. The iron plate, if similarly treated, will lose its charge by the slow oxidation of the spongy iron, but will not be in any way permanently injured.

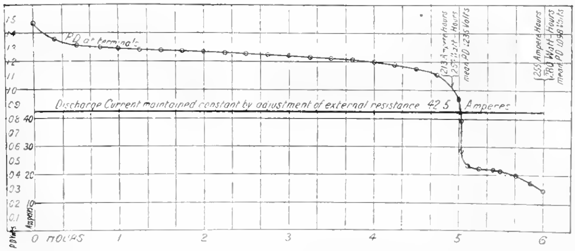

FIG. 2.—Curve of discharge of Edison cell weighing 25 pounds.

Perhaps the consideration that appeals most directly to motor-car users is lightness, or large storage capacity per unit weight. In this respect the cell compares very favourably with lead accumulators. According to Dr. Kennelly the storage capacity of the modern lead accumulator is from 4 to 6 watt-hours per lb., or from 9 to 13 watt-hours per kilogramme, whereas the Edison cell is said to have a capacity of 14 watt-hours per lb. (31 watt hours per kilogramme). It will be interesting to examine these figures a little more closely to see whether this claim to an increased storage capacity of about 3½ times is in reality justified. We reproduce in Fig. 2 a discharge curve for an Edison cell weighing 25lbs., discharging at 42·5 amperes for six hours. It will be seen that after five hours' discharge the voltage drops from 1·45 to 1·0 volt; although it may be possible to obtain the remaining hour's discharge without injury to the cell, yet it is very questionable whether this extra energy at so low a voltage as 0·5 volt would be found useful in practice. We are quite justified in saying, therefore, that this cell is only capable of giving five hours' discharge at 42·5 amperes, thus having a capacity of 213 ampere-hours, or 260 watt-hours. It has, therefore, a capacity of 10 watt-hours per lb. (22 per kilogramme), a figure somewhat lower than that given by Dr. Kennelly in the body of his paper. In an article on accumulators which appeared recently in the *Electro-Chemist and Metallurgist* (May 1901, p. 116), Mr. J. H. West gives a carefully calculated table of the capacities of all the principal accumulators exhibited at the Paris Exhibition or which took part in the Automobile Club competition of 1899. We can take from this table the figures relating to accumulators having a capacity of 200 ampere-hours and discharging in five hours, which are exactly comparable, therefore, with the Edison cell, the discharge curve of which is given in Fig. 2. Calculating from these data we get the results given in the accompanying table; there are 19 cells included in Mr. West's list, but as some of these are heavy cells intended for stationary work, a mean result has been worked out in which the heavier cells are neglected as well as a mean for the whole number.

TABLE.

Cell	Energy stored	
	Watt-hours per kilogramme	Watt-hours per pound
Mean of all cells in Mr. West's table	7	3
Mean of lighter cells ,, ,,	13	6
Lightest cell (Sherrin) ,, ,,	26	12
Edison's cell, from curve	22	10
,, ,, Dr. Kennelly's figures...	31	14

As the figures given by Mr. West only refer to ampere-hours, we have assumed in calculating the table that the mean voltage during discharge is 1·85 volts, a somewhat low estimate, and one therefore favouring the Edison cell in the above comparison. It will be seen from this table that the Edison cell when compared with the lightest lead accumulator obtainable is by no means so pre-eminent as regards energy capacity per unit weight. The Sherrin cell, it may be remarked, came very successfully through the Automobile Club's competition, being the only one which did not fall below the specified voltage more than three times during the trials. Although the figures given above may seem to militate against the claims advanced in favour of the new battery, it must be remembered that high storage capacity is not the only advantage that it is said to possess; even if it were no better than lead cells in this respect, if it proves superior to them in the other four conditions it will be a great advance. Also it must not be forgotten that the cell is quite new and that no doubt great improvement may be looked for when it is produced in large quantities.

THE BIOLOGY OF MOUNT SHASTA.

THE results of a biological survey of Mount Shasta, California, are contained in a *Bulletin*[1] recently received. This publication of 169 pages, with forty-six text illustrations and five heliotype plates, is a worthy successor to its forerunners, now so well known, and in every respect equal to the best of them.

It is the result of an investigation by the Biological Division of the U.S. Department of Agriculture under Dr. C. Hart Merriam, chief of the Biological Survey, which was decided upon in 1898, after the completion of the exploration of southern, middle, and north-east portions of the vast Californian area. The great altitude of the mountain (14,450 feet), and its position between the Sierra Nevada and the Cascades of

1 "North American Fauna," No. 16. U.S. Department of Agriculture. Washington: Government Printing Office, 1899.)

Oregon, invest it with an exceptional interest, in relation to the question of the probable limitations in distribution of the animals and plants peculiar to these; and in the end the unexpected result has been obtained that, although the gap between the Shasta and the Cascades is far less than between it and the Sierra Range, and while plants and animals representative of both ranges are present upon it, the Sierra species are predominant.

In the course of the expedition names were given to newly-discovered peaks and canyons, and at points in the ascent favourable for work and observation individual members of the exploring party were left encamped, in one case for a period of well-nigh a couple of months. The net result biologically has been the discovery of five new species of plants, eight of mammals.

The Report opens with a description of the general features of the mountain; and its glaciers, basins, canyons, streams, slopes, timber-lines, and other natural features, are in turn dealt with in an amply and beautifully illustrated manner.

There then follows a systematic report upon the forest trees and a description of the life zones above 5500 feet, that being the altitude of limitation of the "transition zone" of the mountain, the facies of which are those of the surrounding country. The fauna and flora of this are given, and the superposed heights are next dealt with under zones as follows: the Canadian zone, of 2000 feet, which is defined as a "continuous forest of stately trees"; the Hudsonian, also of 2000, the highest of the timber-belts, characterised by the presence of but two species of trees—a hemlock and a white-bark pine; and the Alpine zone, or that occupying the interval between the timber-line and upper limit of plant growth.

The fauna and flora of each of these are in turn given in full in the form of classified lists of species. Then follows a discussion, with comparison, of the boreal flora and fauna of Shasta and the Sierra and Cascades, again with classificatory lists, and of the surrounding gaps and rivers, regarded as barriers to boreal species. The greater part of the Report which remains consists of a systematic list of the mammals and birds of the area, arranged in order of classification, with full diagnoses and measurements, and "remarks" which embody interesting observations on the habits of more especially the burrowing animals. There follows a chapter on the distribution of the Shasta plants. Concerning the zoological synonymy, many who are familiar with Dr. Merriam's work will be prepared for sub-species and what we in Europe are apt to regard as splitting. In this Report there is little of it, and when the richness of the materials which Dr. Merriam and his contemporaries usually command is borne in mind, criticism of this order were best left in abeyance. In the course of the strictly zoological portion of the Report several new text illustrations are introduced, and any more life-like and fascinating than those of the Rock Cony (*Ochotona* [*Lagomys*]), the Mink (*Lutreola*) and Marten, or among the birds, of the Red Tail and the Clark Crow it would be difficult to imagine.

Shasta is characterised by nothing better than its scanty moisture, and the effect of this on the plant population and zonal distribution is fully discussed. We have nought but the highest praise for this Report. It fills us with envy and arouses feelings of mute admiration for the enterprise of Dr. Merriam and his co-workers in the field. It is worthy the nation that will levy a tax to aid in the foundation and maintenance of a university, and where wealth, long lavished on scientific exploration of the land of their birth, is now bringing its reward of commercial prosperity.

THE NADIR OF TEMPERATURE AND ALLIED PROBLEMS.[1]

DETAILS are given in this paper which have led to the following results:—

The helium thermometer which records 20°·5 absolute as the boiling point of hydrogen, gives as the melting point 16° absolute. This value does not differ greatly from the value previously deduced from the use of hydrogen gas thermometers, viz., 16°·7. The lowest temperature recorded by gas thermometry is 14°·5, but with more complete isolation and a lower pressure of exhaustion, it will be possible to reach about 13° absolute, which is the lowest temperature that can be commanded by the use of solid hydrogen. Until the experiments are repeated with a helium gas thermometer filled at different pressures, with the gas previously purified by cooling to the lowest temperature that can be reached by the use of solid hydrogen, no more accurate values can be deduced.

The latent heat of liquid hydrogen about the boiling point as deduced from the vapour pressures and helium-thermometer temperatures is about 200 units, and the latent heat of solid hydrogen is about 16 units.

The order of the specific heat of liquid hydrogen has been determined by observing the percentage of liquid that has to be quickly evaporated under exhaustion in order to reduce the temperature to the melting point of hydrogen, the vacuum vessel in which the experiment is made being immersed in liquid air. It was found that in the case of hydrogen the amount that had to be evaporated was 15 per cent. This value, along with the latent heat of evaporation, gives an average specific heat of the liquid between freezing and boiling point of about 6 When liquid nitrogen was similarly treated for comparison, the resulting specific heat of the liquid came out 0·43 or about 6 per atom. Hydrogen therefore follows the law of Dulong and Petit, and has the greatest specific heat of any known substance.

The same fine tube used in water, liquid air, and liquid hydrogen gave respectively the capillary ascents of 15·5, 2 and 5·5 divisions. The relative surface tension of water, liquid air and liquid hydrogen are therefore in the proportion of 15·5, 2, 0·4. In other words, the surface tension of hydrogen at its boiling point is about one-fifth that of liquid air under similar conditions. It does not exceed one thirty-fifth part the surface tension of water at the ordinary temperature.

The refractive index of liquid hydrogen determined by measuring the relative difference of focus for a parallel beam of light sent through a spherical vacuum vessel filled in succession with water, liquid oxygen and liquid hydrogen, gave the value 1·12. The theoretical value of the liquid refractive index is 1·11 at the boiling point of the liquid. This result is sufficient to show that hydrogen, like oxygen and nitrogen in the liquid condition, has a refractivity in accordance with theory.

Free hydrogen, helium and neon have been separated from air by two methods. The one depends on the use of liquid hydrogen to boil the dissolved gases out of air kept at a temperature near the melting point of nitrogen; the other on a simple arrangement for keeping the more volatile gases from getting into solution after separation by partial exhaustion. By the latter mode of working something like 1/34000th of the volume of the air liquefied appears as uncondensed gas. The latter method is only a qualitative one for the recognition and separation of a part of the hydrogen in air. In a former paper on the "Liquefaction of Air and the Detection of Impurities" (*Chem. Soc. Proc.*, 1897), it was shown that 100 c.c. of liquid air could dissolve 20 c.c. of hydrogen at the same temperature. The crude gas separated from air by the second method gave on analysis—hydrogen 32·5 per cent., nitrogen 8 per cent., helium, neon, &c., 60 per cent. After removing the hydrogen and nitrogen the neon can be solidified by cooling in liquid hydrogen and the more volatile portions separated.

There exists in air a gaseous material that may be separated without the liquefaction of the air. For this purpose air has to be sucked through a spiral tube filled with glass wool immersed in liquid air. After a considerable quantity of air has been passed, the spiral is exhausted at the low temperature of the liquid air bath. The spiral tube is now removed and allowed to heat up to the ordinary temperature, and the condensed gas taken out by the pump. After purification by spectroscopic fractionation, the gas filled into vacuum tubes gives the chief lines of xenon. The spectroscopic examination of the material will be dealt with in a separate paper by Prof. Liveing and myself. A similar experiment made with liquid air kept under exhaustion, the air current allowed to circulate being under a pressure less than the saturation pressure of the liquid to prevent liquefaction, resulted in crypton being deposited along with the xenon.

A study of fifteen electric resistance thermometers as far as the boiling point of hydrogen has been made, and the results

reduced by the Callendar and Dickson methods. A table was given showing the results for seven thermometers, viz., two of platinum, one of gold, silver, copper and iron, and one of platinum-rhodium alloy.

It is noted that the lowest boiling point for hydrogen was given by the gold thermometer. Next to it came one of the platinum thermometers, and then silver, while copper and the iron differ from the gold value by 26 and 32 degrees respectively. The gold thermometer would make the boiling point 23°·5 instead of the 20°·5 given by the gas thermometer. Then the reduction of temperature under exhaustion amounts to only 1° instead of 4° as given by the gas thermometer. The extraordinary reduction in resistance of some of the metals at the boiling point of hydrogen is very remarkable. Thus copper has only 1/105th, gold 1/30th, platinum 1/35th to 1/17th, silver 1/24th the resistance at melting ice, whereas iron is only reduced to 1/8th part of the same initial resistance. The real law correlating electric resistance and temperature within the limits we are considering is unknown, and no thermometer of this kind can be relied on for giving accurate temperatures up to and below the boiling point of hydrogen. The curves are discussed in the paper, and I am indebted to Mr. J. H. D. Dickson and Mr. J. E. Petavel for help in this part of the work.

Helium separated from the gas of the King's Well, Bath, and purified by passing through a U-tube immersed in liquid hydrogen, was filled directly into the ordinary form of Cailletet gas receiver used with his apparatus and subjected to a pressure of 80 atmospheres, while a portion of the narrow part of the glass tube was immersed in liquid hydrogen. On sudden expansion from this pressure to atmospheric pressure a mist from the production of some solid body was clearly visible. After several compressions and expansions, the end of the tube contained a small amount of a solid body that passed directly into gas when the liquid hydrogen was removed and the tube kept in the vapour of hydrogen above the liquid. On lowering the temperature of the liquid hydrogen by exhaustion to its melting point, which is about 16° absolute, and repeating the expansions on the gas from which the solid had separated by the previous expansions at the boiling point or 20°·5, *no mist was seen*. From this it appears the mist was caused by some other material than helium, in all probability neon, and when the latter is removed no mist is seen, when the gas is expanded from 80 to 100 atmospheres, even although the tube is surrounded with solid hydrogen. From experiments made on hydrogen that had been similarly purified like the helium and used in the same apparatus, it appears a mist can be seen in hydrogen (under the same conditions of expansion as applied to the helium sample of gas) when the initial temperature of the expanding gas was twice the critical temperature, but it was not visible when the initial temperature was about two and a half times the critical temperature. This experience applied to interpret the helium experiments would make the critical temperature of the gas under 9° absolute.

Olszewski in his experiments expanded helium from about seven times the critical temperature under a pressure of 125 atmospheres. If the temperature is calculated from the adiabatic expansion starting at 21° absolute, an effective expansion of only 20 to 1 would reach 6°·3, and 10 to 1 of 8°·3. It is now safe to say, helium has been really cooled to 9° or 10° absolute without any appearance of liquefaction. There is one point, however, that must be considered, and that is the small refractivity of helium as compared to hydrogen, which, as Lord Rayleigh has shown, is not more than one-fourth the latter gas. Now as the liquid refractivities are substantially in the same ratio as the gaseous refractivities in the case of hydrogen and oxygen, and the refractive index of liquid hydrogen is about 1·12, then the value for liquid helium should be about 1·03, both taken at their respective boiling points. In other words, liquid helium at its boiling point would have a refractive index of about the same value as liquid hydrogen at its critical point, and as a consequence, small drops of liquid helium forming in the gas near its critical point would be far more difficult to see than in the case of hydrogen similarly situated.

The hope of being able to liquefy helium, which would appear to have a boiling point of about 5° absolute, or one-fourth that of liquid hydrogen, is dependent on subjecting helium to the same process that succeeds with hydrogen; only instead of using liquid air under exhaustion as the primary cooling agent, liquid hydrogen under exhaustion must be employed, and the resulting liquid collected in vacuum vessels surrounded with liquid hydrogen. The following table embodies the results of experience and theory :—

Initial temperature.	Initial temperature.	Critical temperature.	Boiling points.
Liquid helium ? ...	5° ?	2° ?	1° ?
Solid hydrogen ...	15	6	4
Liquid ,, ...	20	8	5 (He ?)
Exhausted liquid air	75	30	20 (H)
52° C.	325	130	86 (Air)
Low red heat ...	760	304	195 (CO_2)

The first column gives the initial temperature before continuous expansion through a regenerator, the second the critical point of the gas that can be liquefied under such conditions, and the third the boiling point of the resulting liquid. It will be seen that by the use of liquid or solid hydrogen as a cooling agent we ought to be able to liquefy a body having a critical point of about 6° to 8° absolute and boiling point of about 4° or 5° absolute. Then, if liquid helium could be produced with the probable boiling point of 5° absolute this substance would not enable us to reach the zero of temperature; another gas must be found that is as much more volatile than helium as it is than hydrogen in order to reach within 1° of the zero of temperature. If the helium group comprises a substance having the atomic weight 2, or half that of helium, such a gas would bring us nearer the desired goal. In the meantime the production of liquid helium is a difficult and expensive enough problem to occupy the scientific world for many a day.

A number of miscellaneous observations have been made in the course of this inquiry, among which the following may be mentioned. Thus the great increase of phosphorescence in the case of organic bodies cooled to the boiling point of hydrogen under light stimulation is very marked, when compared with the same effects, brought about by the use of liquid air. A body like sulphide of zinc cooled to 21° absolute and exposed to light shows brilliant phosphorescence on the temperature being allowed to rise. Bodies like radium that exhibit self-luminosity in the dark, cooled in liquid hydrogen maintain their luminosity unimpaired. Photographic action is still active although it is reduced to about half the intensity it bears at the temperature of liquid air. Some crystals when placed in liquid hydrogen become for a time self-luminous, on account of the high electric stimulation brought about by the cooling causing actual electric discharges between the crystal molecules. This is very marked with some platino-cyanides and nitrate of uranium. Even cooling such crystals to the temperature of liquid air is sufficient to develop marked electrical and luminous effects.

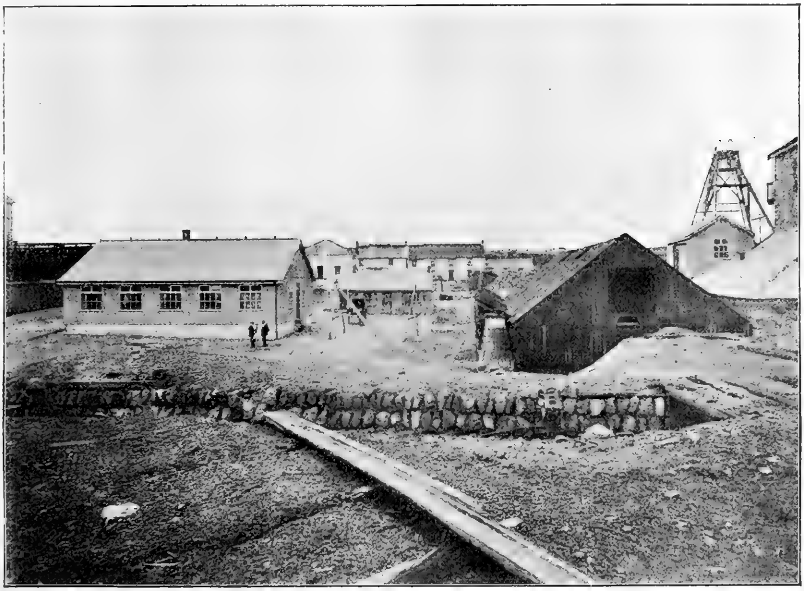
Considering that both liquid hydrogen and air are highly insulating liquids, the fact of electric discharges taking place under such conditions proves that the electric potential generated by the cooling must be very high. When the cooled crystal is taken out of either liquid and allowed to increase in temperature, the luminosity and electric discharges take place again during the return to the normal temperature. A crystal of nitrate of uranium gets so highly charged electrically that, although its density is 2·8 and that of liquid air about 1, it refuses to sink, sticking to the side of the vacuum vessel and requiring a marked pull on a silk thread, to which it is attached, to displace it. Such a crystal rapidly removes cloudiness from liquid air by attracting all the suspended particles on to its surface. The study of pyro-electricity at low temperatures will solve some very important problems.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Education Bill has been abandoned by the Government on account of want of time to consider it adequately during the present session. A short measure dealing with the difficulties which have arisen in connection with the recent judgment as to higher elementary schools and evening continuation schools was introduced in the House of Commons on Tuesday, and it is hoped that the second reading will be taken early next week. The measure proposes to empower county or county borough councils, or technical instruction committees, to make arrangements with School Boards for the continuation during one year of the work to which school funds have been declared to be inapplicable by the Cockerton judgment. Sir Joshua Fitch writes to the *Times* to point out that this measure is unsatisfactory, for it presupposes that a local educational authority to supersede the School Board is intended to be constituted, and meanwhile entrusts the whole responsibility of maintaining or destroying the higher elementary schools and continuation schools to the county councils, which are not necessarily conversant or in sympathy with them. These schools have been created by the School Boards, and in the case of the higher elementary schools the opportunities they give for scientific study and intellectual culture are of the highest value to national progress. What is required is a short Act of Parliament which would, for a year or two longer, leave the management and development of these schools in their present hands and provisionally legalise the needful expenditure from the rates. This, Sir Joshua Fitch remarks, "would simply postpone the controversial parts of the abandoned measure for the maturer deliberation of next session, would provide a satisfactory escape from the present *impasse*, and would, it may be hoped, encounter very little opposition."

giving practical instruction in the use of nautical instruments and in marine engineering. A building is being planned which will afford accommodation for marine engineering, naval architecture and navigation, building construction, joiner's work, and plumbing and metal-plate work, with a lecture theatre and classrooms. Practical classes will be conducted in electrical engineering, especially in connection with ships' lighting. The top floor will comprise a large room for nautical instruments and a room for cartography and the exhibition of ships' models, a chemical laboratory, a balance room, and a physical laboratory. Connected with this floor will be a flat roof on which astronomical observations may be made with such instruments as are used on board ship, and it is probable that a small dome will be provided for an equatorial telescope.

THE prospectus of the mining school at Camborne for the session 1900-1901 tells the tale of some useful educational work which is being carried on in Cornwall. The chief point, and one for which Mr. W. Thomas, the mining lecturer,



Mine Buildings of Camborne Mining School, Cornwall.

deserves great credit, is the existence of a school mine; that is to say, the school is the owner of a tin mine which is worked for educational purposes. Instead of being taught solely by lectures, diagrams and models, the student has to work below ground under the guidance of competent instructors. The school is further equipped with good chemical and assaying laboratories and a special room for teaching the useful Cornish art of "vanning," besides having a large and airy drawing office, a library and a museum. Camborne is close to Dolcoath and other large tin mines, so the student is not confined to the school mine for the purposes of instruction. The fault of the school lies in the fact of many of the lectures being delivered in the evening. Admitting the desirability and necessity of evening classes for young miners who are at work during the day, it seems hard upon the outside student, who is ready to pay full fees, that he should be made to attend lectures from 8 p.m. to 9 p.m., and even later. In the interests of the school this should be changed, even if it necessitates two sets of lectures. The accompanying illustration shows the drawing office, with the mine offices behind it; on the right-hand side

MR. J. PIERPONT MORGAN has given a sum exceeding 1,000,000 dollars for the erection of three buildings for a Harvard medical school.

THE first annual report of the Midland Agricultural and Dairy Institute has been received. The Institute has absorbed the agricultural department of the University College, Nottingham, and now provides courses of instruction in agriculture on practical lines, and calculated to gain the confidence of practical agriculturists. The work is carried on in conjunction with the county councils of Derbyshire, Leicestershire, Lincolnshire (Lindsey) and Nottinghamshire. In addition to courses of instruction for farmers' sons, the Institute undertakes analyses for farmers and conducts experiments of interest to agriculturists at selected centres in the counties named. In a small way its work is similar to that of an agricultural college and experiment station in the United States, and every assistance should be given to enable the work to be extended.

THE Technical Education Board of the London County Council is making arrangements at the Poplar Technical Institute for may be seen the "pit-head frame," with the winding pulleys, which was erected by the students.

THE Technical Education Board of the London County Council is offering facilities for boys who are leaving, or have recently left, public elementary schools to enter upon a course of training which will fit them to become gardeners. A school of practical gardening has been established at the Royal Botanic Society, Regent's Park, and is now attended by some thirty boys, most of whom are holding scholarships from the Technical Education Board. The boys at this school go through a three-years' course, in which they have a thorough training in practical gardening and also receive instruction in elementary science and botany. The scholarships offered by the Board are open to boys between the ages of fourteen and sixteen, whose parents are resident within the County of London and are in receipt of incomes not exceeding 250*l.* a year. The scholarships provide free tuition for three years at the School of Practical Gardening, and also a maintenance grant rising from 20*l.* a year to 25*l.* a year. There is no examination for these scholarships, but parents are required to sign a declaration to the effect that they intend their sons to become practical gardeners. Full particulars of these scholarships, together with application forms, may be obtained from the secretary of the Technical Education Board, 116 St. Martin's Lane, W.C. Application should be made not later than Monday, July 15.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 6.—"On the Elastic Equilibrium of Circular Cylinders under Certain Practical Systems of Load." By L. N. G. Filon, M.A., B.Sc., Research Student of King's College, Cambridge; Fellow of University College, London; 1851 Exhibition Science Research Scholar. Communicated by Prof. Ewing, F.R.S.

The paper applies the equations of elasticity to the investigation of problems connected with the circular cylinder. The solutions are symmetrical about the axis of the cylinder, and are obtained as infinite series involving circular and Bessel's functions.

The three problems treated of are as follows:—

In the first a cylinder under pull is considered, the pull not being applied by a uniform distribution of tension across the plane ends, but by a given distribution of axial shear over two zones or rings towards the ends of the cylinder.

This corresponds to conditions which frequently occur in tensile tests, namely, when the piece is gripped by means of projecting collars, the pull being in this case transmitted from the collar to the body of the cylinder by a system of axial shears.

It is found that the stress is greatest at the points where the shear is discontinuous, *i.e.* at the ends of the collar in a practical case. At these points it is theoretically infinite. For a short cylinder the tensile stress varies a great deal over the cross-section and the distortion of the latter is large.

The second problem is that of a short cylinder compressed longitudinally between two rough rigid planes, in such a manner that the ends are not allowed to expand. It illustrates the crushing of blocks of cement or stone between iron planes or sheets of millboard.

The greatest stress occurs at the perimeter of the plane ends and the "strength" is less than two-thirds of the strength under uniform compression. This result apparently contradicts the fact that the strength of stone or cement, when tested between lead plates, which allow of expansion, is very much less than when tested between millboards; but if we take into account the consideration suggested by Unwin ("Testing of Materials of Construction," p. 419) and corroborated by Prof. Ewing, that lead, which flows easily, may not merely allow, but *force* the expansion of the ends of the block, then it is shown that in tests between lead plates the strength may be much less than between millboards; moreover, such tests are indeterminate. The millboard test should give consistent results, though really introducing too large a factor of safety. The change in the form of the fracture noticed by Unwin is also confirmed by theory.

The third problem is that of the torsion of a bar in which the stress is applied, not by cross-radial shears over the flat ends, as the ordinary theory of torsion assumes, but by transverse shears over the curved surface. This corresponds to the case of a shaft or axle twisted by a frictional couple.

It is shown that the points of danger are those where the applied shear changes discontinuously. At a distance from these the solution rapidly degenerates into the ordinary type.

Physical Society, June 28.—Prof. Everett, F.R.S., vice-president, in the chair.—A paper on the effect of a high frequency oscillatory field on electrical resistance was read by Mr. S. A. F. White. The object of this paper is to discover if the action of light upon the electrical resistance of selenium can be imitated by using high frequency electrical oscillations. It is found that such oscillations permanently increase the resistance of selenium. The effect of a rise of temperature is to increase the resistance of a piece of low resistance and decrease the resistance of a piece of high resistance. The effects of the field in a piece of high resistance can be reversed by exposure to light or by reheating and subsequent cooling. In the case of tellurium a high frequency field temporarily decreases the resistance, as also does a rise in temperature. Repeated heating and cooling of a piece of tellurium permanently increases its resistance. It seems probable that all of the effects are due to rise of temperature caused by minute sparks within the mass. The rise in resistance by alternate heating and cooling may be due to the formation of tellurides with the metal of the electrodes. The large negative temperature effect of tellurium suggests that it might be usefully employed in the detection of heat radiation. The chairman expressed his interest in the paper and drew attention to the very rapid action of light upon selenium. Prof. Adams said that as the effects here noticed were not so rapid as in the case of light they were probably due to change in temperature. Prof. Bose said he had tried the effect of Hertzian radiation upon thin layers of various metals and found an increase of resistance in the case of selenium and a decrease in the case of tellurium. The effect of radiation is confined to a few layers on the surface of the conductor, but it appears that it is of the same nature in continuous solids as in coherers.—A paper by Mr. E. C. C. Baly and Dr. H. W. Syers on the spectrum of cyanogen was read by Mr. Baly. The authors have been able to obtain the spectrum of cyanogen by allowing the pure gas to flow through a vacuum tube and observing from the end of the tube. This is necessary on account of the brown deposit of paracyanogen, which renders observation in the ordinary way impossible. The spectrum obtained differs from the flame spectrum, and consists of a series of equidistant flutings through the whole of the red and yellow somewhat recalling those of the positive band spectrum of nitrogen. The experiments prove that (1) the swan spectrum is not produced by a carbon compound which does not contain oxygen; (2) the swan spectrum is that of an oxide of carbon, as it is only produced by carbon monoxide; and as this spectrum is changed at once into the carbon oxide spectrum by admission of oxygen or by intense electric discharge, and, further, as the carbon oxide spectrum is invariably given by carbon dioxide, there can be no doubt that (3) the swan spectrum is that of carbon monoxide and the carbon oxide spectrum that of carbon dioxide. Mr. Gaster said that this paper might throw light on the discussion of the arc where cyanogen, carbon monoxide and carbon dioxide are present. The presence of cyanogen might be able to explain the hissing of the arc.—The Society then adjourned until next October.

Royal Astronomical Society, June 14.—Mr. E. B. Knobel, vice-president, in the chair.—The secretary read the observations of the great comet of 1901, made at the Royal Observatory, Cape of Good Hope. The comet was first seen on April 24 by Mr. Hills, of Queenstown, Cape Colony, and rapidly became a very brilliant object, with two tails, one conspicuously brighter than the other; the fainter tail was, however, considerably the longer. Photographs taken at the Cape Observatory with a portrait lens and with the McClean 24-inch telescope were shown, and also a drawing made by Mr. Lunt, of the same observatory, which showed several smaller tails between the two main ones. The elements computed gave a parabolic orbit. Mr. Nevill, of the Durban Observatory, who was present at the meeting, said he had received a letter from which it appeared that the comet was seen in Natal the day before it was first detected in Cape Colony.—Prof. Turner gave an account of a paper by Dr. Gill on the Oxford photographic determinations of stellar parallax, and of his own reply. In the discussion which ensued the Astronomer Royal and others called attention to the various irregularities to which stellar photographs are liable.—Lord Rosse read an account of observations of Nova Persei made at the Birr Castle Observatory; further observations by Dr. Rambaut and Mr. Stanley Williams were also read. It appeared that periodical fluctuations in the light of the star (from about magnitude $4\frac{1}{2}$ to 6) still occur, though there no longer seems to be any progressive decrease in its light.—Mr. J. C. W. Herschel read his observations made at Cambridge of the Lyrid meteors.—Mr. Horner read his spectroscopic observations of the sun, made in England about the time of the total eclipse that was visible in Sumatra. He recorded an observation of a most unusually rapid disappearance of a bright solar prominence.—A paper from Prof. D. P. Todd was read, describing a mechanical device for giving graduated exposures in photographing the corona. The method was a modification of that of Mr. Burckhalter, obviating the necessity of using perforated plates.—A paper, by Dr. A. W. Roberts, on the light variations of R. Carinæ, called attention to long and short period variations of a very interesting character.

Zoological Society, June 18.—Prof. G. B. Howes, F.R.S., vice-president, in the chair.—A communication was read from Prof. Ray Lankester, F.R.S., on the new African mammal lately discovered by Sir Harry Johnston in the forest on the borders of the Congo Free State, of which two skulls and a skin were exhibited. Prof. Lankester fully agreed with Sir Harry as to this mammal belonging to a quite new and most remarkable form allied to the giraffes, but having some relation to the extinct Helladotherium, and proposed for it the generic name Okapia, from its native name "Okapi." The scientific name of this mammal would therefore be *Okapia johnstoni*, Mr. Sclater having already given it a specific name based on the pieces of its skin previously received. Sir Harry Johnston, who was himself present, gave an account of the facts connected with his discovery of this animal. Sir Harry also stated that during his last excursion to the north of Mount Elgon he had found large herds of a giraffe in this country which appeared to be distinct from previously known forms of this mammal in having five bony protuberances on the head, four placed in pairs and one anterior in the middle line. Four examples of this animal were now on their way home, and would soon be here to settle the validity of this presumed new species.—The Hon. W. Rothschild, M.P., exhibited and made remarks upon specimens of a mounted male and two unmounted males and a female of the rare Abyssinian goat (*Capra walie*, Rüppell), and of a mounted male of the Abyssinian wolf (*Canis simensis*, Rüppell), which had been obtained by Captain Powell-Cotton during his recent visit to Abyssinia.—Mr. Oldfield Thomas exhibited a pair of antlers which had been sent home by Mr. Charles Hose, who had obtained them from Central Borneo. They appeared to differ from the antlers of all other known deer in being highly complicated and many-branched, with the upper portion curved forward, and the brow-tines developed into broad horizontal paddle-like structures. From this character it was proposed to term the species *Cervus spatulatus*.—Mr. R. Shelford exhibited a series of lantern slides, exemplifying mimicry amongst Bornean insects, especially amongst the Longicorn division of the Coleoptera.—A communication was read from Mr. J. E. S. Moore containing an account of his recent researches on the mollusca of the great African Lakes.—A communication from Captain H. N. Dunn contained field notes on eight species of antelopes, specimens of which he had met with during his recent sojourn on the White Nile in connection with the "Sudd" expedition.—A communication was read from Dr. R. Bowdler Sharpe on the birds collected by Dr. Donaldson Smith during the early part of 1889 in Northern Somaliland. Specimens of 103 species were contained in the collection.—A communication from M. Constantin Saturnin contained a description of a new species of hedgehog from Transcaucasia, proposed to be named *Erinaceus calligoni*. To this was added a revision of the species of the genus Erinaceus of the Russian Empire.—A communication was also read from Mr. J. Lewis Bonhote on the evolution of pattern on birds' feathers, in which it was attempted to show how all the various patterns on the feathers had been derived from a common origin, and were passing or had passed through a definite series of stages before reaching the shapes in which they were found.—Mr. J. Cosmo Melvill read the first part of a paper prepared by himself and Mr. Robert Standen, entitled "The Mollusca of the Persian Gulf, the Gulf of Oman and the Arabian Sea, as evidenced mainly through the collections made by Mr. F. W. Townsend, of the Indo-European Telegraph Service, 1893–1900." The area embraced was determined by an imaginary line (for which reasons were given) drawn obliquely from Cape Ras El Had, below Maskat (lat. 22° 50′ N.), and Panjim, India (lat. 16°). This was the first attempt towards a complete catalogue of the mollusca of this region, between 900 and 1000 species being named, of which more than one-third were of very restricted distribution.

Mineralogical Society, June 18.—Dr. Hugo Müller, vice-president, in the chair.—Mr. Alfred Harker gave a simple proof of the anharmonic ratio of four faces in a zone.—Mr. William Barlow, in continuation of his work on the partitioning of space on the principles of closest packing, exhibited models which presented accurately the symmetry displayed by potassium-alum. The symmetry of various tetartohedral minerals was also explained by the twist which must be given to certain groups of atoms in order to make the packing as close as possible.—Mr. Herbert Smith, in continuation of an examination of crystals of calaverite, showed by means of a gnomonic projection the extremely intricate character of the crystals. The general form suggests monoclinic symmetry, and a well developed face perpendicular to the prism edge frequently occurs; but the symbols which on this supposition must be assigned to the faces are, with few exceptions, very complicated. The majority of the faces lie on a lattice with triclinic symmetry, and of the remainder the majority lie on another lattice inconsistent with the former.—Mr. G. T. Prior pointed out the isomorphous relations between sulphates and orthophosphates as exhibited in a group of rhombohedral minerals, including hamlinite, $AlPO_4.SrHPO_4.Al_2(OH)_6$; florencite, $AlPO_4.CePO_4.Al_2(OH)_6$; beudantite, $Fe'''PO_4.PbSO_4.Fe_2(OH)_6$; svanbergite,

$$AlPO_4.SrSO_4.Al_2(OH)_6;$$

alunite, $AlSO_4KSO_4.Al_2(OH)_6$; and jarosite,

$$Fe'''SO_4KSO_4.Fe_2(OH)_6.$$

Similar relations are also shown by the isomorphous pairs, monazite, $CePO_4$, and crocoite, $PbCrO_4$; fergusonite, $YNbO_4$, and scheelite, $CaWO_4$; herderite, $CaFBePO_4$, and caracolite, $NaCl.PbSO_4$ (?); pharmacolite, $CaHPO_4.2H_2O$, and gypsum, $CaSO_4.2H_2O$.

PARIS.

Academy of Sciences, June 24.—M. Fouqué in the chair.—Chemical equilibria. Reactions of two bases added simultaneously to phosphoric acid, by M. Berthelot. The author has studied the distribution of the bases between the precipitate and solution obtained when sodium hydroxide and calcium (or barium) hydroxide are added to a solution of phosphoric acid. A considerable proportion of the sodium is in every case found to be contained in the precipitate.—On acetylometallic radicles, by M. Berthelot. The composition of the metallic derivatives of acetylene recently described by M. Chavastelon is shown to be capable of being represented in accordance with the views formerly expressed by the author as to the presence of acetylometallic radicles in such compounds.—Synthesis of a colouring matter derived from diphenylenephenylmethane, by MM. A. Haller and A. Guyot. Crystal violet is converted by a series of reactions into the leucobase hexamethyltriamidophenylfluorene which, when oxidised with lead peroxide, yields fluorene blue, $C_{25}H_{28}N_3Cl+2\frac{1}{2}H_2O$. This colouring matter has a bluer tint than crystal violet, but does not differ essentially from the latter as regards its tinctorial properties.—A simple and trustworthy apparatus, capable of easy and rapid application, for facilitating existence and work in irrespirable atmospheres contaminated with deleterious gases, by MM. A. Chauveau and J. Tissot. The essential feature of the apparatus is an arrangement for the separation of the currents of inspired and expired air.—On globular lightning, by M. J. Violle. An instance of globular lightning was observed towards the end of a storm on June 9 last.—Action of an oxide or a metallic hydroxide on solutions of the salts of other metals: mixed basic salts, by M. Paul Sabatier. Observations on a recent paper by M. Recoura.—Third series of observations of the new star in Perseus, by M. H. Deslandres (see p. 240).—On the continuous deformation of surfaces, by M. D. Th. Egorov. Remarks on a recent communication by M. Tzitzeica.—Theory of linear groups in an arbitrary region of rationality, by M. L. E. Dickson.—On the integration of the equation $\Delta w - \mu^2 w = 0$, by M. S. Zaremba.—Chemical reactions in dissolved or gaseous systems. Vapour tension; Avogadro's hypothesis, by M. Ponsot. A continuation of previous papers on the subject, which is treated mathematically.—Capillary constants of organic liquids, by MM. Ph. A. Guye and A. Baud. The results described show that oximes and urethanes resemble alcohols, acids, ketones, &c., in being polymerised in the liquid state. The group of urethanes is remarkable in that the degree of polymerisation *increases* with the molecular weight.—On the preparation of phosphorous oxide, by M. A. Besson. Fresh experiments are cited in proof of the existence of the oxide P_2O, previously described by the author.—On the action of solar radiations on silver chloride in presence of hydrogen, by M. Jouniaux. When sealed tubes containing silver chloride and hydrogen are exposed to sunlight, metallic silver is formed, and, under favourable conditions, the whole of the hydrogen is eventually converted into hydrogen chloride.—Action of mercuric oxide on aqueous solutions of metallic salts, by M. A. Mailhe. The action of freshly precipitated mercuric oxide on the chlorides, nitrates and sulphates of manganese, cadmium, lead and iron is described. With sulphates no reaction occurs, as a rule, but the chlorides and nitrates are decomposed with the formation of mixed basic salts.—Observations on basic salts containing several metallic oxides, by M. G. André. A number of complex salts were described by the author some years before the recent experiments of MM. Mailhe and Recoura.—Action of bases and acids on the salts of amines, by M. Albert Colson. Former experiments on this subject are continued.—On racemic erythritol, by MM. L. Maquenne and Gab. Bertrand. Griner's experiments are confirmed and extended. The four theoretically possible stereoisomeric erythritols are now known.—Action of acid chlorides on aldehydes in presence of zinc chloride, by M. Marcel Descudé. The action of acid chlorides on aldehydes is greatly facilitated by the presence of a trace of zinc chloride.—Nitration of acetylacetic ethers and their acid derivatives, by MM. L. Bouveault and A. Bongert.—On the acidimetric value of parasulphanilic acid, by M. G. Massol. A thermochemical paper.—On racemism, by MM. J. Minguin and E. Gregoire de Bollemont. The properties of a number of racemic camphor derivatives are compared with those of their active constituents.—Synthesis of boronatrocalcite (ulexite), by M. A. de Schulten. The artificial mineral may be obtained by adding calcium chloride to a large excess of cold, saturated borax solution, and leaving the mixture at rest for fifteen to thirty days.—On the commencement of germination and the evolution of sulphur and phosphorus during this period, by M. G. André.—Morphology of the digestive apparatus of Dytiscus, by M. L. Bordas.—On the sensibility of higher plants to the useful action of potassium salts, by M. Henri Coupin. The growth of wheat is shown to be favoured by almost infinitesimal quantities of potassium salts.—On the constitution of the seed of Hernandia compared with that of Ravensara, by M. Édouard Heckel.—Use of the Oudin resonator for the production of X-rays, by M. R. Demerliac.—On the presence and localisation of iodine in the leucocytes of normal blood, by MM. Stassano and P. Bourcet. The small quantity of iodine contained in normal blood exists exclusively in the leucocytes.—On the production of local anæsthesia in dental surgery by means of currents of high frequency and intensity, by MM. L. R. Regnier and G. Didsbury.—On the conservation of mineral waters, by M. F. Parmentier.

THURSDAY, JULY 11, 1901.

ROTHSCHILD'S NOVITATES ZOOLOGICAE.

Novitates Zoologicae. A Journal of Zoology in connection with the Tring Museum. Edited by the Hon. Walter Rothschild, Ernst Hartert and Dr. K. Jordan.

IT has long been the custom of some of the principal museums of natural history in all parts of the world to maintain a periodical devoted, more or less exclusively, to the publication of the discoveries made by the members of their staffs and based on the collections placed under their care. The long series of *Annales du Musée* and *Archives du Musée* issued by the naturalists of the great French museum in the Jardin des Plantes are well known to all workers in biology. The National Museum of Holland issues its *Notes from the Leyden Museum* with great regularity, and of not less importance to zoological science are the *Annals* of the Museo Civico of Genoa. On the other side of the Atlantic, we find the *Bulletin* of the American Museum of Natural History at New York, and the similar publication of the National Museum of the U.S. at Washington, both mainly devoted to the work performed by the naturalists of those institutions, and in South America the Museums of Parà and S. Paulo issue corresponding publications. One advantage of this plan is that it helps to make the existence of the museum and its working staff more generally known, and another that it supplies a convenient medium for the exchange of publications with other similar institutions.

Shortly after Mr. Walter Rothschild had founded the Zoological Museum at Tring, in order to house his large collections, and to render them more accessible for scientific research, he wisely determined to establish an illustrated periodical for the publication of the results of his own work and that of his fellow-labourers in the new institution.

Novitates Zoologicae is the appropriate title of this "organ," and quite deserves its well-chosen name. Beginning in 1894, it has now completed its seventh annual volume; and the eighth (for 1901) is in full swing. But before we speak of the contents of this work, a few words may be said about the building in which Mr. Rothschild's treasures are housed, and which stands in a quiet corner of the little town of Tring on the borders of Tring Park. Lord Rothschild's son has been from early youth a devoted student of natural history of all kinds, and has well employed his almost unrivalled opportunities for hunting up new and rare specimens in every quarter of the globe. Active agents under his directions have explored the mountains of New Guinea, the little-known islands of the Northern Pacific, and the forests of South America with great success, and have reaped a large harvest of zoological specimens which have accumulated under his care. After the collections thus made had outgrown the accommodation that could be given to them in a private establishment, Mr. Rothschild determined to establish a building for their special reception. This was accomplished about 1891, when a museum, plain in structure, but admirably adapted to its object, arose, under Mr. Rothschild's directions, at the corner of Tring Park, and has since that period become famous amongst naturalists as the "Zoological Museum, Tring."

The Tring Museum consists of two departments—the public galleries and the working laboratories. The galleries contain a fine series of mounted specimens illustrative of all the leading orders of animals and admirably mounted and arranged for the edification of the general public, who are admitted to inspect Mr. Rothschild's treasures four days in the week. Mammals, birds, reptiles, fishes, insects, shells, corals, sponges and other marine animals crowd the shelves, and amongst them are many specimens of special interest on account of their rarity or remarkable forms. The mammals and birds of the British islands are specially attended to, and a cabinet of glazed drawers, accessible to every visitor, contains a nearly complete series of British butterflies and moths, which renders the identification of these insects easy to the inquirer. Amongst the rarities in the order of mammals is a stuffed specimen of the extinct quagga (*Equus quagga*), one out of the four or five still known to exist in European museums. Another nearly extinct mammal well represented at Tring is the white or square-mouthed rhinoceros of South Africa (*Rhinoceros simus*). Two of the few remaining examples of this huge animal were shot in Mashonaland by Mr. R. T. Coryndon in 1892. One of these is now in the British Museum, while the other was secured by Mr. Rothschild. The specimen in the Tring Museum, which has been splendidly mounted by Messrs. Rowland Ward and Co., stands more than 6 feet at the withers, and is upwards of 12 feet in length. It is the original of the excellent figure of this species given in the Zoological Society's *Proceedings* for 1894. In the bird-series, humming-birds, parrots, game-birds, apteryxes and cassowaries are some of Tring's strongest points, whilst the set of bones of the extinct *Æpyornis* of Madagascar is unrivalled, and will strike everyone with admiration.

Such are some of the more striking objects in the public galleries of the Tring Museum, but still more important are those stowed away in the laboratories where Mr. Rothschild's naturalists, Mr. Ernst Hartert and Dr. Jordan, will be found hard at work. Mr. Hartert devotes his time mainly to birds of all classes, of which there is a splendid series at Tring. Dr. Jordan bestows his attention on the invertebrates, and especially on the lepidopterous insects, or moths and butterflies, in many branches of which the Tring collection is almost unrivalled. Both these naturalists, as well as Mr. Rothschild himself, publish most of their contributions to science in *Novitates Zoologicae*, of which we have given the title at the head of this article, although contributions are likewise made to the *Novitates* by many other specialists, to whom specimens are sent from the Tring Museum for examination and description. Seven bulky volumes of this excellent periodical have now appeared, and the eighth is in rapid progress. They are, we need hardly say, printed in excellent type and on good paper. They are also accompanied by numerous beautiful plates drawn by the best zoological artists of the day for the illustration of the special novelties described in the text.

Commencing with the first volume, which appeared in 1894, we find articles on mammals, birds, reptiles and insects of the orders Lepidoptera and Coleoptera. Fifteen coloured plates illustrate this volume, amongst which we may call special attention to that of a new lemur from Madagascar, *Propithecus majori*, drawn by Keulemans.

The second volume (1895) is nearly of the same character, and contains, amongst other rarities, a figure of the very remarkable duck *Salvadorina waigiouensis*, lately discovered in the little-known island of Waigion, the last place, perhaps, in which one would have thought of looking for a merganser. In this volume also will be found a description of some very interesting remains of the extinct gigantic bird of Madagascar (*Æpyornis*) prepared by Mr. C. W. Andrews, of the British Museum; also a beautiful figure (by Keulemans) of a new and most magnificent bird of paradise, *Astrapia splendidissima*, based on a specimen in the Tring Museum which is said to have come from the foot of the Charles Lewis mountains in Dutch New Guinea.

We need not recapitulate the contents of the following five volumes, which, however, are all of great zoological interest. But we may allude to some of the most extraordinary novelties illustrated, amongst which are (in vol. iii.) a very remarkable new Picarian bird from Madagascar, *Uratelornis chimaera*. In vol. iv. will be found figured another new and extraordinary bird of paradise, described by Mr. Rothschild as *Loboparadisea sericea*.

In vol. v. are pictures of two beautiful new tanagers, discovered by Mr. Rothschild's collector, Rosenberg, in North-western Ecuador.

In vol. vi. is given a figure of a new and gigantic tree-kangaroo (*Dendrolagus maximus*) lately discovered in Dutch New Guinea. This volume likewise contains an elaborate essay by Mr. Rothschild on the kiwis or apteryxes of New Zealand, with a chapter on their anatomy by Mr. F. E. Beddard, F.R.S., illustrated by numerous plates.

In vol. vii. (1900) will be found the conclusion of an important monograph on the butterflies of the genus *Charaxes* and the allied forms, prepared by Mr. Rothschild in conjunction with Dr. Jordan, and accompanied by numerous illustrations, which was commenced in vol. v. It will be evident, therefore, we think, that, as already stated, Mr. Rothschild has selected a most appropriate title for the organ of the Tring Museum, and has been very successful in his search for the subjects to which its pages are devoted.

THE METRIC SYSTEM.

Le Système Métrique. By G. Bigourdan. Pp. vi+458. (Paris: Gauthier-Villars, 1901.) Price fr. 10.

M. G. BIGOURDAN, of the Astronomical Observatory of Paris, has published a work with the object, apparently, of showing how leading a part France has taken in the introduction and propagation of the international metric system of weights and measures. The book, however, tells one nothing new, for cannot all it tells be found as to early history in "Base du Système Métrique" (1806, 1821); as to subsequent development in the works of Barny, Saigey, Tarbé, Leoni-Levi, the second report of the Standards Commission (1869), &c.; and as to latest scientific data in the *Proc. Verb. et Trav. et Mem. du Bureau International des poids et mesures* (Gauthier-Villars, 1875–1900)? Many of these publications are, however, difficult to obtain, and hence M. Bigourdan has met a want by putting together under one cover all available information with reference to the origin, construction and verification of metric standards.

In these days of advertisement some readers fight shy of log-rolling works, of the dishing-up of old books under new titles, of the re-editing of other men's labours, and perhaps of the literature of metric propaganda there has been enough. In the present work, however, the temptation to advertise appears to have been avoided, and the compiler has simply given, in a careful, concise and exhaustive manner, the results of the labours of the eminent chemists, physicists and mathematicians—as Arago, Benoit, Berthollet, Bertrand, Borda, Broch, Cornu, Delambre, Deville (H.), Faye, Fizeau, Foerster, Lagrange, Lalande, Laplace, Lavoisier, Stas, Tresca, &c.—who have made the metric system the only international system for all purposes.

The book contains thirty-three chapters, the first of which deals with the weights and measures in use in France previous to the revolutionary period, and to the hypotheses of Bailly and Paucton with reference to uniformity. Then follow chapters referring to the proposition of Talleyrand to the General Assembly of France in 1789; to the decrees of that Assembly in 1790 establishing a new and uniform system of measurement; and to the establishment (under the Metric Convention of 1875) of the Comité International des poids et mesures. This Comité was thus one outcome of the original proposition of 1789—a remarkable outcome generally, seeing that it changed the weights and measures of nearly the whole of Europe, and swept away native and arbitrary metrological systems which had been handed down from primitive times; systems embarrassing to scientific progress, hurtful to commerce and a tax on intelligence.

M. Bigourdan (p. 14) seems to say that in 1790 some communication was made by France to England as to the adoption of a new international base of measurement. No such communication was, however, made either through the Foreign Office or officially to the Royal Society; nor was England then invited to take part in the establishment of the metric system.

An interesting account is given by the author of the founding of the Bureau International (Pavillon de Breteuil, Sèvres, près Paris); of the construction of the new international standard of the metre, and of the kilogramme; made of platinum (90 per cent.) and iridium (10 per cent.); and which were in 1889 deposited at the International Bureau, where they are still kept. An account is also given of the verification of the étalons-nationaux, or copies of the étalons-internationaux, which have now been distributed to the high contracting states who have joined the Convention of 1875. The national standard metre and kilogramme, which were issued by the Comité to Great Britain, are referred to in the Metric Act of 1897.

With reference to the determination of the length of a linear measure, as the metre, by spectroscopic reference to rays of light, Prof. Michelson and Dr. Benoit obtained remarkable results in 1892–3.

Reference is also made by M. Bigourdan to the researches of Drs. Chappuis and Guillaume as to the mass of 1000 cubic centimetres of water at 4°. They find that a cubic decimetre of water weighs 999·936 grammes (p. 413) or 1 kg.–64 mg. Prof. D. Mendeléeff has, however, stated the mass of a cubic decimetre of water at 4° as 999·847 grammes (*Proc. Roy. Soc.*, 1896, p. 155).

The book contains seven interesting portraits of Talleyrand, Delambre and others; also an alphabetical list of more than 400 authors and persons who have taken part in the introduction and verification of metric standards, and a useful chronological table of French laws and ordinances (1557–1896).

We no longer now regard the metre as the length of 1/10,000,000th part of the quadrant of the meridian, or the kilogramme as the precise weight of a cubic decimetre of distilled water. Such derivations and definitions have proved a failure, and very much of the information set out by the author with reference thereto, although of historic interest, might well be condensed in the next edition of the book.

PROF. MAX MÜLLER'S LAST ESSAYS.

Last Essays. By the Right Hon. Prof. F. Max Müller. 1st series. Pp. vii + 360. (London: Longmans and Co., 1901.) Price 5*s.*

THE seventeenth volume of the late Prof. Max Müller's "Collected Works" contains a series of essays on language, folklore and other subjects which were selected for publication by the venerable scholar about the time that his illness assumed its last acute form; but, alas! he never lived to expand and annotate, according to his wont, such as had already appeared in print before. The greater number of them treat, as we should expect, of the subjects of which he had made a close and lifelong study, and these bear in every paragraph evidences of the clear thought and brilliant exposition which all Prof. Max Müller's readers were accustomed to expect from that expert philologist. In two of them, "My Predecessors" and "How to Work," we get a few glimpses of the man as well as of the scholar, and they cannot fail to interest all those who wonder from time to time how one man, with so many varied interests and occupations, could manage to do so much good work in a single lifetime. In "How to Work" we see the leading ideas which he kept ever before him whilst carrying on his labours of copying manuscripts, editing texts and the like, and when we read the advice which he gave to the students of Manchester College in 1896 we are able to note that we are reading the words of a man who practised what he preached. He said, "Put your whole heart, or your whole love, into your work," and "half-hearted work is really worse than no work"; it is a pity that, like the verses from the Koran which are writ large and hung up on the walls of the mosques where all men may see and read them, these excellent words cannot be copied in large letters and set before the eyes of our boys and girls in schools and colleges. Of equal value is his counsel to them to make indexes to the books that they read, and he pointed his moral admirably when he told them how he worked with slips when making his *index verborum* to his great edition of the "Rig-Veda." But then Prof. Max Müller belonged to a school which produced such scholars as Fleischer, Lepsius, Bühler, Rödiger and Hoffmann, and we cannot help doubting if their modern representatives have the inclination or can find the time to make tens of thousands of index slips. The social life of Universities, even in Germany, makes it more and more difficult for a man to devote years, or months, to tasks of this kind, and a professor finds that lectures, committee meetings, &c., use up, and alas! sometimes waste, a great deal of his time.

The essay on "Coincidences" will be read by every one who is interested in the study of comparative religion with the deepest interest, for in it is demonstrated with considerable clearness and with incontrovertible proofs, if we accept the facts set out by Prof. Max Müller, that Christianity owes much to Buddhism. The Roman Catholic missionaries Huc and Gabet, while travelling in Thibet in 1845, discovered to their horror that the Buddhist priesthood possessed the crosier, the mitre, the dalmatic, the cope, the service with two choirs, the psalmody, exorcism and prayer-beads, and that the celibacy of the priesthood, spiritual retreats, worship of saints, fastings, processions, litanies, holy water, &c., were as much the characteristics of the Buddhist as of the Roman Catholic religion. After thinking the matter over for some time the Christian missionaries made up their minds that these resemblances were the work of the Devil, who wished to lead astray any missionary who ventured to travel in Thibet, and now we know that an actual historical communication existed between Roman Catholic and Buddhist priests. It has recently been proved that the Buddhist Canon was collected at the Council held B.C. 259. at Patna by Asoka, and that the Pâli Canon of Buddhism was written down in the first century before our era, and that the Sanskrit Canon was written down in the first century after. Thus it seems clear that if any borrowing at all took place between the two religions, the Christian borrowed from the Buddhist, and not the Buddhist from the Christian. This need cause no surprise, for, apart from the well-known historical connection which existed between the Buddhists and Nestorians in the seventh, eighth and ninth centuries, there was undoubtedly frequent communication between India and Persia and Asia Minor from the time of Alexander the Great. The Buddhist religion was, like the Christian, a missionary religion, and in proof of this Prof. Max Müller has adduced some very interesting facts.

There are many other essays in the volume to which we should, if space permitted, like to call attention, and among them are those on "The Savage" and "Literature before Letters." The former was first printed in 1885 in the *Nineteenth Century*, and we cannot help thinking that had its learned author lived to see it reprinted he would have modified several sections of it; the latter is full of interest, as much for the subject of which it treats as for the indications it gives of Prof. Max Müller's extraordinary power of memory. Finally, Oxford men will read with pleasure the appreciation of the late Dean Liddell which is found on p. 314 *ff.*; and historians of modern Europe will find much information on the famous Schleswig-Holstein Question in the last essay in the volume. It is almost superfluous to add that the style in which the essays are written is clear and fluent, and we are sure that even the scientific opponents of the great Sanskrit scholar will be glad to possess in a collected and handy form some of the last writings of a man who has scored his mark broadly and deeply upon the edifice of Indian philology.

HETEROCYCLIC ORGANIC COMPOUNDS.

Die Heterocyklischen Verbindungen der Organischen Chemie. By Edgar Wedekind. Pp. iv + 458. (Leipzig: Veit and Co., 1901.) Price 12 marks.

THE author of the book before us states in his preface that his object is to extend those chapters of the elementary treatises on organic chemistry which deal with heterocyclic derivatives, to supply a text-book of the subject for the use of advanced students and the technical chemist, and thus to render unnecessary the possession of exhaustive and expensive text-books.

But, with the best will in the world, we regretfully come to the conclusion that the work is of very slight practical value; heterocyclic derivatives are frequently derived from straight chain compounds possessing complex molecules, and the chemist will find himself compelled to refer to one of those works Dr. Wedekind would avoid the use of in order to elucidate the synthesis of the heterocyclic ring.

One example of this difficulty, which may, indeed, be met with on almost every page of the book, will suffice; speaking of the methods of formation of osotriazoles, we find given as the second method: "intermolecular separation of the elements of water from the hydrazo-oximes of 1 : 2-diketones

$$\begin{array}{l} R.C{=}N.NHC_6H_5 \\ \quad | \\ R.C{=}N.OH \end{array} \quad \rightarrow \quad \begin{array}{l} R.C{=}N \\ \quad | \\ R.C{=}N \end{array}\!\!\!> NC_6H_5."$$

Now unless the student or technical chemist had made a special study of the hydrazo-oximes he would possess the vaguest idea of their method of formation, and would have to refer to a text-book. A well-known and inexpensive work of this nature ("Organische Chemie," Richter, ninth edition), under the heading α-hydrazo-oximes, describes, not only the formation of these bodies, but also, on the same page, their intramolecular condensation to the heterocyclic ring.

Dr. Wedekind has adopted an empirical classification which brings substances of most dissimilar constitution under the same heading; for example, in the group—Hetero-rings containing five members:

I. Oxygen as member of the ring.

(1) Single rings with one oxygen,

we find the following bodies, which possess slight genetic connection: furfuran, tetramethylene oxide, γ-lactones, and anhydrides of the acids of the succinic series (it is true the author announces his intention of passing over reduced and easily resolvable rings, such as anhydrides and lactones; but to be consistent, should not a reduced ring, such as piperidine, be also ruled out of court?)

Nor does Dr. Wedekind's system even possess the merit of originality; this system first appeared in the seventh (German) edition of Richter's "Organic Chemistry," and has been adhered to in subsequent editions; it was adopted by Brühl from Anschütz and Schroeter (editor and sectional editor of the above work) in his continuation of the German translation of Roscoe and Schorlemmer's "Organic Chemistry" (vols. vi. and vii.).

The genetic or rational system of nomenclature was adopted by Krafft in 1893, and is to be found, further freed from empiricism, in the last instalment of Meyer and Jacobson's "Organic Chemistry" (the group of the polynucleic benzene derivatives, 1901).

A due sense of the proportionate importance of certain classes of bodies is frequently absent; thus the very important purine group is dismissed in a few pages as an appendix to the benzopyramidine group, purines being considered as glyoxalinepyramidines.

For the rest, the book, which contains an enormous amount of information, seems carefully compiled, up-to-date and accurate; we prefer to find the references at the foot of the page instead of being collected at the end of the first and of the second part; out of 1475 references there are fifteen to English publications, which, considering the amount of work which has been done in this country on heterocyclic rings, seems scarcely a fair proportion.

In view of the facts that the ninth edition of V. von Richter's "Organic Chemistry" (Anschütz-Schroeter) has appeared, and that Messrs. Veit and Co. promise the rapid completion of Meyer and Jacobson's admirable handbook, we can only repeat that such books as the one which forms the subject of this notice are completely superfluous. W. T. L.

OUR BOOK SHELF.

The Induction Motor. A Short Treatise on its Theory and Design, with numerous Experimental Data and Diagrams. By B. A. Behrend. Pp. 105. (New York: *The Electrical World and Engineer*, 1901.)

MR. BEHREND, in the preface to his book, rather offers an apology for adding one more to the already overwhelming number of books dealing with electricity and its applications. In some cases an apology of this kind is, unfortunately, justified; but in this instance, in view of the very great importance of the subject from the electrical engineer's point of view and the increasing introduction of polyphase electrical installations, a work on the above subject, written by a writer who, from his continental experience, should know what he is talking about, is to be welcomed. The author's point of view is made clear by a quotation from Prof. J. J. Thomson, printed on the title-page: "The absence of analytical difficulties allows attention to be more easily concentrated on the physical aspects of the question . . . than if he merely regarded electrical phenomena through a cloud of analytical symbols"; and on a first glance at the book, which consists of only 105 pages, one had hoped for a concise and easily comprehensible statement of the subject. This cannot, however, be said to be the case. The book could be very conveniently entitled "A notebook for the designer of induction motors," and to an electrical engineer well versed in polyphase work it would be, without doubt, very useful. The reader who does not possess these qualifications will not find it of much value. The author admits this, in that he adds an appendix containing an extract from Gisbert Kapp's "Electric Transmission of Energy," dealing with the elementary theory of the induction motor, and says that after reading this the reader will be better able to understand his own diagrams and deductions. We think, however, that the author would have done well had he made his reasoning a little more clear and detailed. The method adopted is the graphical method, a diagram being given for each machine, &c., considered. The diagrams are given without, in some cases, any of the reasoning which leads up to them. This to the engineer who thoroughly understands the subject does not matter, and to such we would recommend the book. Besides dealing with the general calculations concerned with single and polyphase motors, one chapter is devoted to the special design of a three-phase motor of 200 h.p.; and two chapters, the first and the last, deal with the theory of the alternating current transformer. In appendix ii. a graphical method is given for integrating some of the equations given in the body of the book. We think it is possible for this so-called "non-mathematical" treatment to be carried a little too far. The electrical engineer who does not wish to be severely handicapped in his profession must be able to work out an integration without having recourse to a roundabout method to avoid it, which is most likely only applicable to the particular case under consideration.

Bulletin of the Philosophical Society of Washington. Vol. xiii. 1895–1899. Pp. xxvi + 507. (Washington, D.C.: Judd and Detweiler, 1900.)

THE subjects of papers included in this volume are:—Central American rainfall, a transcontinental series of gravity measurements, cloud classifications, steel cylinders for gun construction, the latitude-variation tide, Alaska, graphic reduction of star places, chemistry in the United States, the transcontinental arc, a century of geography, the comparison of line and end standards, recent progress in geodesy, secular change in the direction of the terrestrial magnetic field at the earth's surface, and the function of criticism in the advancement of science. In addition, there are a number of obituary notices of members of the Society.

Several of the subjects of the papers have already been referred to in these columns, and as the papers go back to March 1895, it is a little late to describe them in any detail. The volume is of particular interest to students of geodesy and physical geography, the papers on the measurement of arcs for the determination of the size and shape of the earth, and on gravity observations, being full of information. The results of a series of gravity measurements, made by Mr. G. R. Putnam, lead to the conclusion that "general continental elevations are compensated by a deficiency of density in the matter below sea-level, but that local topographical irregularities, whether elevations or depressions, are not compensated for, but are maintained by the partial rigidity of the earth's crust." Gravity measurements made on the summit of Pike's Peak and at Colorado Springs, near the base, give the value 5·63 for the mean density of the earth. A discussion of Mr. Putnam's gravity observations leads Dr. C. K. Gilbert to agree that they "appear far more harmonious when the method of reduction postulates isostacy than when it postulates high rigidity."

At the close of a paper on the transcontinental arc measured by the U.S. Coast and Geodetic Survey, Mr. E. D. Preston refers to the accuracy of the observations, and remarks: "The quality of the triangulation is best shown by a comparison of bases. The Fire Island one, nearly 9 miles long, was determined in five different ways through 1800 miles of triangulation, and the extreme range of the results is only two-tenths of a metre. The value from Kent Island base, 5 miles long and 263 miles away, only differed from that given by the Atlanta base, nearly 6 miles long and 868 miles away, by one centimetre."

The paper on the secular change in the direction of the terrestrial magnetic field at the earth's surface, by Mr. G. W. Littlehales, contains a number of valuable plates showing curves of the secular motion of the magnetic needle for twenty-nine different places.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the Theory of Temporary Stars.

IN a note read before the Royal Astronomical Society on May 10, Father Sidgreaves offers a suggestion regarding the displacement of the dark bands in the spectrum of Nova Persei which seems to obviate the serious difficulty felt by astrophysicists in the explanation of the shift of the lines on Doppler's principle.

The ingenious idea set forth in this note—emanating, apparently, from so high an authority as Lord Kelvin—certainly goes far to explain the singular fact that the displacement of these dark bands in the Novæ should *always* be towards the more refrangible side. But Father Sidgreaves remarks that the suggestion does not "help us over the second difficulty: the great breadth of the bright lines, some of which seemed to have lost nothing in width up to the last days of April." The following remarks may perhaps contribute towards an explanation of this second phenomenon, and may thus form a theory supplementary to that proposed in Father Sidgreaves' note.

First of all, it ought to be remarked that the structure of the bright bands, when seen with high dispersion, is extremely complicated. In Nova Aurigæ, as well as in the present new star, the bands were observed to consist of several bright maxima separated by darker interstices. Sir Norman Lockyer, in his communication to the Royal Society on March 28, presented some exceedingly interesting diagrams, exhibiting the intensity curves of the bright hydrogen bands in Nova Persei. Sir Norman shows that these bands consisted of at least three, and in the case of $H\beta$ of even four, maxima. The very same structure appears in the chief nebula band at $\lambda = 501$, as is

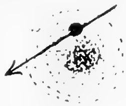

FIG. 1

shown by the measurements made with the Cooke spectroscope of this Observatory, an account of which will shortly be published.

In the note referred to, Sir Norman Lockyer has already suggested that we have here "indications of possible rotations or spiral movements of two distinct sets of particles, travelling with velocities of 500 and 100 miles per second." It appears, therefore, that the extreme width of the bright bands is not caused by a continuous broadening of the line—such as, for instance, increased pressure would produce—but by the juxtaposition of several lines belonging to the same substance, but of somewhat different wave-lengths owing to motions in the line of sight. An explanation of the width of the bright bands is thus equivalent to giving a sufficient reason for the production of displacements such as would conduce to the peculiar grouping of the maxima in the bright lines of the spectrum of new stars.

Father Sidgreaves starts from the assumption of "a collision between two stars." We shall here proceed from the hypothesis propounded by Prof. Seeliger, of Munich, that the Nova is due to the phenomenon of a dark body impinging upon and penetrating into a mass of nebular material.

Now it seems extremely unlikely that the density of the matter composing the nebula should be the same throughout. There will in all probability be a condensation of this matter round the centre, or centres, of gravity of the mass, so that the density must be assumed to decrease outwards from this centre. I consider an assumption of this kind to be warranted, if not demanded, by our modern views regarding the evolutions of stellar systems. But if a body flying through space should approach such a mass, the probability is very small that its line of motion would pass directly through the centre of gravity. Hence we are fairly warranted in assuming that the path of the body through the nebula will lie somewhere between its centre and its boundary (Fig. 1).

In such a case the friction on the surface of the body, caused by its motion through the resisting medium must be greater on the side next the centre of the nebula than on the side next its boundary. This difference of resistance must obviously result in imparting to the impinging body a rotatory movement.

Of course a tremendous translatory velocity would be required to produce any sensible motion of rotation in the impinging body itself. But by following Prof. Seeliger's reasoning it becomes easy to understand how even a comparatively small translatory motion suffices to originate enormous gyratory movements in the strata of the atmosphere surrounding the body. Obviously, the immediate consequence of a collision between body and nebula will be a superficial heating of the former and the resulting formation of an incandescent atmosphere around it. Now Prof. Seeliger has pointed out that the attraction of the body on the nebular mass through which it travels must greatly enhance the relative velocity of those particles which pass near the surface. In his opinion, "no extravagant assumption is required to obtain very great velocities for these particles, velocities such as have been proved to exist in the case of Nova Aurigæ." Hence, even when the initial translatory motion is small, the attractive force of the body would cause enormous differences of velocity between the impinging particles of the cosmical cloud and the atmosphere of the intruding body. And

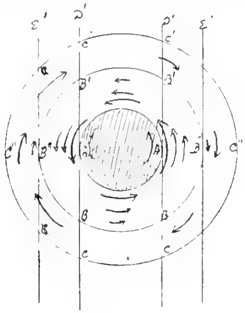

FIG. 2.

it is easy to perceive that, in case of a preponderance of impacts on one side over those on others, there must result a gyratory movement of the atmosphere, the velocity of which will, in course of time, become much of the same order as that of the impinging nebular matter.

The assumption of a cosmical cloud, the density of which increases towards the centre of gravity, leads, therefore, to the necessary conclusion that the incandescent gaseous matter near the body must assume a vorticose motion of probably very high velocity. This motion has its maximum near the surface of the body, whence it will grow less with increasing distance from the centre.

According to the fundamental laws of gyration the rotatory motion must vanish at a certain distance, beyond which it will assume the opposite direction. Let Fig. 2 represent a section through the centre of the vortex in a plane perpendicular to its axis of rotation. Let AA be the surface of the body, BB the locus of the stationary sphere separating the two oppositely-gyrating systems, CC the outermost boundary of the whole system of gyration. Then we have between A and B a rotatory motion of high velocity in *one* direction, decreasing in amount from A towards B, and a rotatory motion in the opposite direction between B and C of less average velocity than the former. The space from A to C is filled with incandescent nebulous matter, the maximum incandescence being at A, whence it decreases towards C. The space beyond C, on the other hand, is filled with nebulous matter of low temperature and no rotatory motion.

The whole vortex travels, of course, along with the central body in a certain direction. This obviously imparts to the light emitted by *every* particle of the whole system exactly the *same* displacement, and hence the motion of translation may be left out of consideration in questions dealing with *relative* velocities.

The assumption made so far, that the rotation of the particles takes place in circles concentric with the circumference of the body, must, however, be modified. The fan-like action of the body's atmosphere will draw in towards the poles of rotation quan-

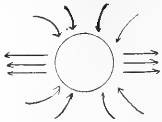

FIG. 3

tities of nebulous matter which, yielding to centrifugal force, will flow towards the equator, and be thence projected outwards again. The nature of this action may best be seen by considering a section of the system in a plane passing through the centre of the vortex and in the direction of the axis of rotation. The figure so obtained (Fig. 3) is precisely the same as that arrived at by Dr. Siemens in his ingenious theory of the conservation of solar energy. (NATURE, March 9, 1882.) In fact, the conditions postulated by Dr. Siemens in his theory—viz., that the sun is surrounded by matter in a rarefied form, filling interplanetary and even interstellar space—are precisely the conditions under which the phenomenon of a new star is here supposed to occur.

We have, then, to expect an indraught of cool nebulous matter at the poles of the intruding body, and an outflow in all directions of hot nebulous matter at its equator.

In spite of the apparent complexity of the different motions involved in the gyration here described, it is comparatively easy to indicate the influence they must have on the appearance of the lines of a substance present in the nebular matter. Let us first consider the influence of the *tangential* components of the gyratory motion.

Reverting to Fig. 2, and assuming AD to be the direction of the line of sight, it is clear that in the space AADD we have to deal with an incandescent nucleus AA whose light is intercepted by incandescent matter at a lower temperature between A and C, and by dark nebulous matter of still lower temperature between C and D. The resultant effect would be exactly that which Sir William Abney has described in *M. N.* xxxvii. p. 278. The displacements of the line in opposite directions from the normal caused by the approach and recession of the limbs of the rotating body and its atmosphere would broaden the absorption band, which would therefore appear dark in the centre and would gradually shade off towards the edges. The intensity curve of

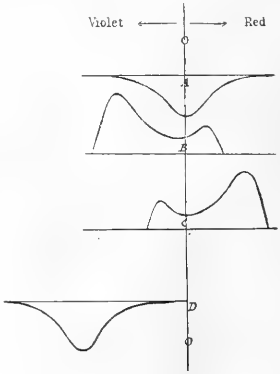

FIG. 4.

the band produced by this part of the gaseous envelope, still provided there be no *radial* motion of matter in the vortex, would thus be similar to that exhibited in curve A in Fig. 4.

Taking next the segment BAB′B″ on the left hand side of the figure, we have a motion of the incandescent nebulous matter *towards* us. We must therefore expect a bright line displaced towards the violet. The maximum intensity of this line will be near the edge farthest from the normal position, and it will gradually dim off in brightness as the normal wave-length is approached. This dimming off, which is chiefly the consequence of decreasing incandescence with decreasing rotatory motion, is enhanced by the absorbing action of the cool substance in the outer rings of the vortex. For this matter, having no motion with a direction *towards* us, can absorb only those wave-lengths which coincide with its own, viz. those emanating from the incandescent matter at and near the arc BB″B′, while it leaves the light of higher wave-lengths emanating from A unaffected.

If we now consider the conditions prevailing in the annular section BCC″C′B′, we see at once that the motion of the particles is here in the opposite direction, viz. away from the earth. The light emanating from these particles will, therefore, be displaced towards the red, and consequently a bright line must appear on the less refrangible side. But the velocity of motion in the line of sight in this annular section is smaller than at A, and the incandescence of the particles much inferior; hence the maximum intensity of this new line will not be so far from the normal wave-length, and the line will also be fainter than that on the violet side described before. Taking into consideration these circumstances, we may then assume that the intensity curve resulting from the whole radiation in the segment C′C″CA on the left hand side of Fig. 2 is approximately represented by the curve B in Fig. 4. The radiation of the corresponding segment on the right hand side of Fig. 2 must obviously be the image of B in the normal OO′, and is thus represented by C of Fig. 4.

As all the light emanating from the star must be supposed to pass through the slit of the spectroscope, the line seen in the spectrum will be the resultant of all the component curves. Clearly the character of this compound line remains unaltered, whatever position the line of sight may have with reference to the motion of the star or to the axis of gyration, except the one case when the line of sight is parallel to this axis. Obviously the band would then be reduced to a single line at normal wave-length. The probability of such an occurrence is, however, excessively small. Hence the theory here advanced would lead us to accept the peculiar character of the bright lines exhibited in the curves B and C of Fig. 4 as *a feature characteristic of the whole class of temporary stars.*

So far we have traced the structure of the line emitted by a substance of the nebulous matter on the assumption of circular rotatory movements. We have still, however, to take into account the influence of the flow of this matter to and from the centre of the vortex, as indicated in Fig. 3.

The cool matter flowing in at the poles of the vortex must be supposed to be in a non-luminous condition. It can neither radiate nor absorb selectively in the way as Kirchhoff's law would require, and hence it has no effect on the structure and position of the bright and dark bands. The hot and incandescent matter flowing out at the equator, however, has an important influence in this respect. Reverting to Fig. 2, it may be readily seen that the radial component of the motion of the gaseous particles within the space A A D D included between the two tangents to the surface of the body is directed *towards* the sun. Consequently the absorption bands caused by these particles must all appear displaced towards the violet. Thus, instead of curve A in Fig. 4, which represents the intensity of these bands when there is no radial motion, we obtain curve D of the same figure as the actual representation of the intensity of these bands in the spectrum. The striking difference between A and D is therefore the considerable displacement towards the more refrangible side of the absorption band in D. No matter what direction the line of sight has with regard to the motion of body or nebula, or whether we consider a section through the vortex at right or oblique angle to the axis of gyration, in all cases, except the one mentioned above, *the displacement of the absorption bands must be towards the more refrangible side.* The effect of the radial components of the gyratory motion on the position of the bright bands is easily seen from a consideration of the conditions prevailing in the segments C C″ C′ A in Fig. 2. Apparently there are as many motions towards as there are away from the sun. Hence the effect will consist in a general broadening of the four maxima represented in B and C of Fig. 4, without, however, affecting their position relatively to the normal wave-length.

The combination of B, C and D in Fig. 4 will therefore approximately represent the complete intensity-curve of a line emitted by a substance in the gaseous envelope of the Nova. The combination of B and C alone represents the structure of the bright bands; it agrees perfectly with the drawing given by Sir Norman Lockyer for the case of $H\beta$. Often enough the two inner maxima may overlap each other and thus produce the impression of a single strong maximum at normal wave-length. This would explain the curves with only three maxima exhibited in the diagrams of Sir Norman's paper.

There can be no doubt that the absorption band in D will partly interfere with the maximum of the emission band on the violet side. As a rule the former may be assumed to be the more refrangible, since its displacement must be enhanced by the expansion of body and vortex as a consequence of increased production of heat. In the case of Nova Persei, the difference in the displacement owing to this latter effect must have been very considerable; the two bands were here placed beside each other with comparatively little encroachment of the one upon the other. The conditions in Nova Aurigæ appear to have been somewhat different. Here the displacements of the emission and absorption bands seem to have been fairly equal, the latter obliterating the former almost completely. I consider the bright lines noticed in almost all the absorption bands of this Nova to be the remnants of the more refrangible maxima of the bright bands.

In any case the effect of a partial encroachment of the absorption band upon the emission band must be a displacement of the centre of the bright band towards the red. We therefore derive two most important results from the theoretical considerations here given:—

(1) *In all the temporary stars the absorption bands must be displaced towards the more refrangible side.*

(2) *In all the temporary stars the centres of the emission bands must show displacements towards the less refrangible side.*

These conclusions are in entire accordance with the facts. As already mentioned, an exception may happen when the line of sight is approximately parallel to the axis of gyration. In this case both the emission and absorption lines would appear in their normal positions, since all the vortex-motions are then more or less perpendicular to the line of vision. Hence the two lines would overlap each other almost completely, and the result would be a purely continuous spectrum with little or no traces of selective absorption or emission. Such an exceptional case many perhaps have presented itself to our eyes in Nova Andromedæ.

The new star in Perseus, thanks to its discovery by Dr. Anderson almost immediately after its appearance in the heavens, offered to astronomical science the unique opportunity of recording the initial stages of its development. None of the theories hitherto propounded have so far succeeded in accounting for the spectral changes so markedly exhibited in the star's light during the first days of its existence as a radiating celestial body. But just these quite unexpected and at first sight perplexing changes find a marvellously simple explanation by the modification of Prof. Seeliger's nebular theory here offered. The first effect of the collision between the dark body and a cosmical cloud must be an enormous heating of the body's surface and the generation of an incandescent atmosphere around it. The depth of this "cloak" of incandescent matter will at first be small, so that the star at that time presents the aspect of a luminous nucleus surrounded by a comparatively shallow atmosphere of incandescent gases. The spectrum yielded by such a star must be continuous, showing dark lines generated by the absorbing faculty of the glowing gases between the nucleus and space. At the moment of the outburst these dark lines will be exceedingly faint, and they will show only such a displacement as is necessary from the amount and direction of the translatory motion of the body. As time passes, however, and the gyration of the atmosphere becomes stronger, the outward flow of the hot particles must rapidly increase, and thus, in accordance with the developments given above, the dark lines, while becoming broader and more distinct, must gradually shift towards the more refrangible side. This increase in the displacement of the dark bands during the first days has been actually observed by Prof. Vogel and many other spectroscopists. To yield a *bright* line spectrum the incandescent atmosphere must have attained a considerable depth, otherwise the bright lines emanating from particles in the space CC″C′A would make no marked impression on the vividly luminous continuous background. Hence we conclude that the bright bands can only appear with sufficient distinctness when the gyratory motion has attained considerable velocity. This is exactly the sequence of the phenomena observed immediately after the outburst.

In the beginning the attracted nebular particles will impinge directly on the surface of the dark body, and hence the heat developed will mainly serve to raise the temperature of this surface. But after gyration has set in, the direct contact between the outside nebula and the body's surface is greatly lessened by the interference of the vortex. The attracted particles will then impinge upon the vortex-rings by which many of them are deflected into circular orbits and thus prevented from colliding with the surface. It is therefore conceivable that the incandescence of the nucleus, after having attained a maximum very soon after the collision, decreases again when the vortex motion gains in power. After a time, the incandescence of the nucleus will be chiefly maintained by the friction between the vortex and the surface. The star's radiation must therefore ultimately attain a lower limit where it becomes stationary so long as the vortex motion is constant. This state appears to have been reached by Nova Persei towards the middle of March.

The variability of the star is a natural consequence of this theory. We have only to suppose that the dark body, when entering the cosmical cloud, had no sensible rotation of its own. In this case the impacts would be more frequent, and consequently the incandescence more vivid, on one part of its surface than on others. Now, when the gyratory motion has become considerable, the friction between vortex and body must gradually impart a slow rotatory movement to the latter. Thus, by rotation, the patch of greater luminosity would at times be revealed to us, while at other times it would become invisible.

In conclusion I shall mention a fact revealed by the observations which speaks greatly in favour of the theoretical views set forth in this paper. Whenever the continuous spectrum of the Nova became feeble, the green band at $\lambda = 501$ was seen to gain considerably in breadth and brightness. Now a reduction of the intensity of the continuous background must obviously be accompanied by a decrease in the intensity of the absorption bands. If the nucleus were to lose its radiating power altogether, these bands would naturally become emission bands. In such a case the bright bands of the spectrum would therefore appear much broader and more intense. Hence any reduction in the general emissive power of the nucleus must tend to increase the width and brightness of the spectral lines.

That the spectrum gradually changes from the chromospheric to the nebular type is exactly what must be expected from the foregoing considerations. I need scarcely say that the theory is sufficiently flexible to adapt itself to any kind of hypothesis which may be made with regard to the physical constitution of the nebular matter. Considering the enormous forces which must have been developed in the impacts, I incline to the opinion that, besides a gaseous fluid, we are probably here in presence of cosmical matter of a meteoritic constituency such as Sir Norman Lockyer assumes in his well-known theory.

I am fully aware that the explanations I have been able to give in this communication can only be a first approach to the comprehension of a phenomenon which is necessarily one of extreme complexity. Considering, however, that the theory here advanced is based upon assumptions which seem to me perfectly warranted and highly probable, and that the prominent facts brought out by the spectroscope are satisfactorily explained by it, I venture to submit it even in this preliminary state to the criticism of astronomers. It is certainly the first time that the ingenious theory of Dr. Siemens has been called upon to explain a phenomenon in the remote recesses of the universe, and I am confident there must be many admirers of this eminent man of science who would wish to find his excellent theory applicable to the extraordinary case of stellar evolution before us.[1]

My best thanks are due to Mr. G. Clark, of this Observatory, for several suggestions which proved to be most valuable for the above investigation.

J. HALM.

Royal Observatory, Edinburgh, June.

[1] It is worthy of remark that a terrestrial cyclone, if the velocities therein exhibited were vastly greater than they actually are, and if its centre were occupied by a radiating nucleus so hot as to make the gyrating gases incandescent, would present to an outside observer exactly the same structure in the bands of its spectrum as is exhibited in the case of Nova Persei.

Vitality of Seeds.

THE resistance of the dormant protoplasm of seeds to low temperatures has lately received much attention. C. de Candolle, Pictet, Brown and Escombe and Sir W. T. Thiselton-Dyer have in succession extended our knowledge of the resistance of seeds towards extremely low temperatures. The last-mentioned experimenter has shown that very various seeds do not lose their germinating power after being exposed to the temperature of liquid hydrogen.

The upper limit of temperature which seeds can resist does not seem to have been carefully ascertained. It is probable that it would vary with different seeds and for the same seed when containing different percentages of water. For it is known that the coagulating point of proteid depends, within certain limits, on the amount of water present in it. Thus Lewith (*Arch. für exp. Pathol. u. Pharmak.* 1890) showed that proteid containing 25 per cent. of water coagulates at 74°–80° C., containing 18 per cent. at 80°–90° C., and with 6 per cent. only at 145° C. It follows that if it is the coagulation by heat of the proteids of the seed which prevents the embryo returning from its state of suspended animation into active vitality, the resistance of the seed will depend on its state of desiccation.

With this idea I have been making a few preliminary experiments on desiccated seeds, and I find that in every case they can resist surprisingly high temperatures. At first I thought it necessary to desiccate the seeds over sulphuric acid for a fortnight or longer before raising their temperature considerably. I now find it as effective, and more convenient, to dry the seeds on an oven for a day at 65°–75° C., and then for a day at 90° C. After this they may be raised to successively higher temperatures without harming them till their upper limit is passed. All the seeds I have tested can resist a temperature of at least 100° C. The following are the species I experimented with:—*Avena sativa*, *Lolium perenne*, *Lactuca sativa*, *Helianthus argophyllus*, *Mimulus moschatus*, *Medicago sativa*, *Brassica Rapa*, *Eschscholtzia californica*, *Papaver somniferum*, *P. nudicaule*, *Meconopsis cambrica*, *Schizopetalon Walkeri*.

Of these Medicago has proved the most resistant. After an exposure of one hour to 110° C. and then of one hour to 121° C., 10 per cent. germinated.

The effect of exposure to the high temperature is, however, noticeable in all cases by the marked retardation of germination and by the extremely slow growth afterwards. The young plants, too, seem weakly, and there is a distinct loss of sensibility to the geotropic stimulus in their radicles. Whether they would ultimately become normal I cannot say, as the conditions under which they were germinated were not suitable for further development.

For most of the other seeds the upper limit seems to be considerably lower. It lies about 110° C. Perhaps, however, by more careful desiccation even these less resistant ones may be brought into a condition to stand exposure to higher temperatures. The following table will convey some idea of these preliminary experiments, showing the upper limit and the retarding effect of exposure to high temperatures for each species.

The Roman numerals indicate the number of days between moistening and germination as indicated by the protrusion of the radicle.

Temperatures	15°	97°	100°	105	107°	108°	110°	112°	114°
Avena sativa	iii	vi	v	iv	—	—	xi	—	—
Lolium perenne	v	iv	iv	v	xii	—	xii	—	—
Lactuca sativa	ii	ii	ii	ii	vi	—	viii	xii	xviii
Helianthus argophyllus ...	iv	iii	iii	iv	xi	—	xi	—	—
Brassica Rapa	ii	ii	—	iii	vi	vi	viii	—	—
Eschscholtzia californica...	ii	iii	ii	ii	ii	—	vii	—	—
Mimulus moschatus ..	—	vii	ix	xviii	—	—	—	—	—

From this table the increase in the time needed for germination is apparent. All the samples of seeds were sown on moist sand simultaneously, and maintained under conditions of temperature and moisture as similar as possible.

For the other seeds not mentioned in this table the time needed for germination was not recorded, and only the maximum temperature resisted was observed. These maxima were as follows: *Schizopetalon Walkeri*, 105°; *Papaver somniferum*, 100°; *P. nudicaule*, 100°; *Meconopsis cambrica*, 100°; *Medicago sativa*, 121°.

This great resistance of dried seeds to comparatively high temperatures naturally calls to mind Prof. Giglioli's most remarkable experiments with regard to the actions of poisons, both gaseous and liquid, on seeds. An account of them was given in NATURE, 1882, p. 328, and 1895, p. 544. He found that dried seeds of *Medicago sativa*, although exposed to the prolonged action of gases such as oxygen, chlorine, nitric oxide, &c., and of poisonous fluids, *e.g.* alcohol, corrosive alcohol, &c., retained their power of germination. In some of his experiments the time of immersion of the seeds in the poison was so prolonged (many years) that the supposition of the non-penetration appeared precluded. I have repeated Giglioli's experiments with several species, and found, as he did, that some seeds can withstand the action of poisons while others cannot. Seeds of *Medicago sativa* were exposed from 10–30 days to the action of methylated spirit, spirit saturated with mercuric chloride and with picric acid without their powers of germination being noticeably affected. Similarly, seeds of *Papaver Rhoeas*, *P. somniferum* and *Schizopetalon Walkeri* resisted the action of spirit, but were apparently killed by corrosive alcohol. *Papaver Rhoeas* germinated after two days' immersion in chloroform and two days in spirit. On the other hand, seeds of *Nicotiana Tabacum*, *Linaria reticulata*, *Gypsophila paniculata* and *Calandrina umbellatum* did not germinate after immersion in spirit.

The following experiment shows, I think, that this astonishing resistance to poisons is not due to the quiescent state or stability of the protoplasm of the seed, but to the imperviousness of the seed-coat. A large number of seeds of *Medicago sativa* were taken, and half of them were punctured with the prick of a needle. All were then desiccated, and after desiccation immersed some in spirit, some in spirit and mercuric chloride and some in spirit and picric acid. It was then found that the intact seeds germinated in large quantities even after immersion in the poisonous fluids, while the punctured seeds germinated in no case after immersion. In a control experiment it was found that the punctured seeds both before and after desiccation germinated freely. It would appear, then, that when the penetration of the poison was secured the effect was to destroy the vitality of the seed.

Botanical Laboratory, Trinity College, Dublin.

An Instance of Adaptation among the Deer.

MY friend Major C. S. Cumberland has just brought from Manipur the head and hind-foot of a deer, the latter of which affords an interesting instance of adaptation to environment. The deer in question is the Manipuri representative of the thamin (*Cervus eldi*) of Burma, an animal inhabiting open tree jungle. The Manipur valley is, however, a huge swamp, and the thamin of that locality have developed a peculiar modification in the foot which enables them to walk with ease in such ground. In the Burmese thamin the under surface of the hind pasterns is covered with hair in the ordinary manner, and the animal walks entirely on the main hoofs, keeping the pasterns much elevated. In the Manipuri thamin, on the other hand, the under surface of the pasterns is covered with a hard, horny, bare skin, which immediately above each hoof has almost the consistency of horn, and is practically continuous with the hoof itself. Moreover, so far as can be determined from comparison with a mounted specimen of the Burmese form, the pasterns are very considerably longer than in the latter. In walking, according to the account given by Major Cumberland, the foot is much bent, so that the animal walks on nearly the whole of the under surface of the pasterns, and thus gains a firm support on the yielding morass.

Assuming this feature to be constant (as Major Cumberland believes to be the case), the Manipuri thamin appears entitled to rank as a distinct local form, for which the name *C. eldi cornipes* will be appropriate, Major Cumberland's specimens standing as the type.

But, quite apart from this minor point, the specimens are of especial interest as showing a previously unknown mode by which ruminants may adapt themselves to a life in swamps. In the well-known instance of the sitatunga antelope of Africa a sufficiently large surface of support is afforded by a lengthening of the hoofs; in the present case the hoofs remain of the normal length, and support is obtained by the animal walking on the under surface of the pasterns, which is specially hardened. It is, in fact, an incipient instance of the reversion of a digitigrade animal to the plantigrade progression of its swamp-dwelling ancestors.

R. LYDEKKER.

Snow Conditions in the Antarctic.

THE meteorologist of my expedition has unfortunately given a somewhat incorrect idea about the snow conditions at Cape Adare. He reports, namely, that there is a very small snow fall at the sea-level. This is, in my opinion, not the case. But his mistake is excusable and easily explicable; of course, being a young Tasmanian and not previously having seen ice and snow, a devotee to his instrument, took down in his note book the evidence of a usual snow gauge. Snow seldom or never fell in the Antarctic except during heavy gales, and it must be clear to anybody familiar with snow that a snow gauge of the ordinary type is worse than useless during heavy gales. Although Cape Adare itself and the peninsula on which we lived were almost free of snow in the open, we had more than ten feet of snow to the leeward of our hut at Camp Ridley, and undoubtedly there would have been still more had the huts been higher. This indicates, of course, that much snow fell, but it was blown away as well from the promontory at Cape Adare as from the unfortunate snow gauge. In my opinion a very heavy snow fall takes place within the Antarctic circle. And I believe that the strong gales within the Antarctic circle generally are local and that these snow bared dark promontories are the very homes of the Antarctic gales, while those places where no dark land is to be seen probably are unmolested by great atmospheric disturbances and are therefore covered in heavy snow. From time to time in the pack ice I have passed through distances where the ice was covered in several yards of loose snow. This I noticed as well on my first voyage in 1894 as during my last expedition. I will therefore use the opportunity to warn the coming expeditions from not providing against the difficulties which a very heavy snow fall incurs for sledge parties within the Antarctic circle.

Douglas Lodge, Bromley, Kent, July 6.

PHOTOGRAPHIC AND PHOTOMETRIC SURVEYS OF THE STARS.[1]

EVERYONE will naturally wish to offer words of hearty congratulation to Sir David Gill and his able coadjutor, Prof. Kapteyn, on the completion of the Cape Durchmusterung, of which the third and last volume has recently appeared. Some twenty years since, when the capacity of celestial photography was practically an unknown factor, Sir David Gill proposed to himself to complete a survey of the southern hemisphere by means of photographic star maps. The original conception was a tolerably modest one. Sir David Gill's idea was simply to prepare from these maps a working catalogue of stars to facilitate the meridian zone observations, after the programme of the Astronomische Gesellschaft, but "to avoid the repetition of such an arduous undertaking as Argelander's Durchmusterung as a preliminary step." How the original plan was extended and grew, till the results fill three bulky volumes, exceeding Argelander's work both in number of stars and in accuracy of observation, he has himself told in the introduction to the first part, to which we have already referred (NATURE, vol. lvii. p. 513). Very rapidly has the work gone on once all preliminary difficulties were removed, and now the astronomers of the Cape and of Groningen see their work completed on a uniform plan within a moderate space of time, with an accuracy which approaches that attaching to the older so-called "Precision Catalogues," together with the means existing for the determination in special instances of star places with even greater accuracy. For though we have spoken of the completion of the work,

[1] "The Cape Photographic Durchmusterung for the Equinox 1875." By David Gill, C.B., LL.D., F.R.S., &c., His Majesty's Astronomer at the Cape, and J. C. Kapteyn, Sc.D., &c., Professor of Astronomy at Groningen. Part iii. Zones −53° to −89°. Pp. 88+671. (Edinburgh: Neill and Co., 1900.)

"A Photometric Durchmusterung, including all Stars of the Magnitude 7·5 and brighter North of Declination −40°, obtained with the Meridian Photometer during the Years 1895–98." By Edward C. Pickering, Director of the Harvard College Observatory. Pp. 330. (Cambridge, U.S.A., 1901.)

this is to be understood in a limited sense. The discussion of the catalogue is about to begin. Such discussion will include the examination and detection of errors in the "Precision Catalogues," the search for, and discovery of, stars with large and unsuspected proper motions, and the formation of a catalogue of variable stars for the southern hemisphere. Further, the course of the work has disclosed the existence of a possible systematic difference of colour in stars, depending on the galactic latitude, and intimately connected with this inquiry is the investigation of the systematic corrections which should be applied to the magnitudes derived from the Cape plates to ensure one uniform system, photographically considered, or to connect the photographic and optical magnitudes. A revision conducted on such ample lines is a task of only less magnitude than that of the construction of the catalogue itself, while the importance and interest are even greater. That the same competent hands will carry such a discussion to a final issue will be the hope and the expectation of all astronomers.

The introduction supplied by Prof. Kapteyn to the third volume cannot possess the novelty and the interest which naturally attaches to that accompanying the first volume of the annals. In that it was necessary to detail his scheme of measuring the plates and effecting the reduction; he also sketched the results at which he had arrived by comparison with the work made on the meridian by other astronomers, pursuing similar but less extensive methods. The subsequent volumes have had to record the mechanical accumulation of the places and magnitudes of stars observed by the same method, till we have piled up for us the enormous total of 454,384 stars, catalogued within an area of 13,911 square degrees, embraced in the district between the South Pole and the parallel of 19° south declination. The greater richness of the southern skies is shown by the fact that this number is only slightly less than that contained in the joint Durchmusterung of Argelander and Schonfeld, extending from the North Pole to 23° south declination. Further, this richness has increased as the observations have been carried polewards, the maximum being reached in the zone 48°–58° S. decl. In the first section, comprising the zone 18°–37° S. decl., the average number of stars to a square degree was 25·43 (Nature, *loc. cit.*); for the whole the average number is 32·66, or more than double that of the Northern Bonn Durchmusterung. But in a discussion involving relative density of aggregation the vexed question of the maintenance of a uniform standard of magnitude throughout the whole survey enters with perplexing uncertainty. On this point Prof. Kapteyn entertains views into which we do not care to enter too minutely, for we are yet awaiting his complete answer to sundry criticisms which have been advanced. We are certainly inclined to follow him in his assertion that if two or three tenths of a magnitude be deducted from the estimates we shall obtain the limit of photographic magnitude to which the stars of the catalogue are certainly practically complete, and that consequently we may assume the whole catalogue to embrace all stars down to 9·2 mag.

There is, however, the other and more thorny question, which touches on the relative chemical activity of stars in different parts of the sky, which it is not so easy to answer. Prof. Kapteyn puts the question thus. To what limit of magnitude would the plates be found complete were the magnitudes of the Cape Durchmusterung reduced to a homogeneous set of photographic magnitudes for the whole sky? The answer which he offers is that the Durchmusterung will be found practically complete in or near the Milky Way, to stars which in the scales of Schonfeld, of Gould and of Thome are of the magnitude 9·5, and for the rest of the sky to stars actinically equivalent to these. The vagueness of this reply is due to the peculiar feature that Prof. Kapteyn's discussions have disclosed, and whose complete explanation is not yet forthcoming. The measurement of a great number of plates has satisfactorily shown that the law expressing the growth of star density depending on proximity to the Milky Way differs essentially from that exhibited in the optical observations of Schonfeld and Gould. For this fact two explanations, equally plausible, can be offered. Prof. Kapteyn's contention is that there is a real difference in the colours of the stars as the Milky Way is approached, and that the increase of blueness leads to increasing discrepancies in the differences between photographic and visual magnitude, amounting roughly to 0·01 mag. for each degree of galactic latitude. On the other hand, the ground for the observed inequality may be due to systematic errors in assigning the optical magnitudes to stars under the different condition in the method of selection of the stars, when they pass slowly in the sparser regions of the sky, and when the richer regions are being observed. The tendency might very well be, from the greater time at the disposal of the observer in the first case, to observe fainter stars than when he finds his field crowded with passing objects. Of course, both views were fully admitted by Prof. Kapteyn, but he considered he had sufficient evidence to establish his case, and though he acknowledges the force of the arguments which have been brought against him, he is still inclined to maintain his view. The fuller discussion is one of those points which have been left for future investigation so as not to delay the completion of the main work, but if the Groningen astronomer can obtain support for his theory it may have an important bearing on our views concerning the cosmical arrangement of the stars.

The accuracy of the stars' coordinates remains practically the same as in the earlier volumes, and from a comparison with Gould's meridian places may be given as follows:—

Declination.	Prob. Error in Right Ascension.	Prob. Error in Declination.
$-38°$ to $-58°$	$\pm 0^s{\cdot}288$	$\pm 0'{\cdot}0444$
$-58°$ to $-86°$	$\pm (0^s{\cdot}157 + 0^s{\cdot}0764 \sec \delta)$	$\pm 0'{\cdot}0559$

But the method of measurement of stars on the polar plate affords a better means of determining the degree of accuracy attainable on these plates, and of the possible service they are likely to render in settling questions of identity or of proper motion. On this plate the rectangular coordinates have been measured with the Repsold apparatus acquired by the astronomical laboratory at Groningen, and the measures reduced by comparison with all the stars (save one) common to the plate and to Gould. Making due allowance for proper motion and error of observation in the Cordoba places, the probable errors of the Cape positions are found to be in R.A. $\pm 0''{\cdot}53$ (arc of great circle); in decl. $\pm 0''{\cdot}76$.

Considering the shortness of the focal length (54 inches) such a result is extremely gratifying, and it seems likely, as anticipated by the authors, that many questions connected with the proper motion of the southern stars can be at once set at rest by an appeal to the original plates. Some such work seems to have been already begun, judging by the tables added to the volume, in which are shown instances of stars missing on the plates and yet given elsewhere, and of stars found on the plates not recorded in known catalogues. Such work requires infinite patience and care, and we can only once more congratulate the joint authors on the success that has attended their unwearied efforts to secure uniformity and accuracy.

The second work under notice also exhibits the results of continued labour pursued with persistence and success. Photometry has so long been a feature in the researches at Harvard College Observatory, and so many successive volumes have detailed the method of observing, that on the present occasion the Director contents himself with a very short preface, but which gives evidence of the same untiring energy which marked the earlier volumes. For example, we are told that between 1891 and 1898 no less than 473,216 photometric settings were made with the meridian photometer, nearly all by the Director himself. The object of this heavy undertaking was to determine the magnitude of all stars brighter than 7·5 situated north of $-40°$ declination. In the early days of magnitude work the Director did not propose to pass the limit of $-30°$. This restriction was perhaps necessary on account of the smaller photometer employed, but to overstep it may also indicate that the Director feels himself now competent to cope with the difficult questions arising from the extinction of light in our atmosphere. For, although the Durchmusterung does not aim at completeness beyond $-40°$, a good many stars, reaching to even within one degree of the Harvard horizon, have been included. Such measures are necessarily frequently discordant among themselves and do not agree with the estimates made in the southern hemisphere, but the discussion of all the discordant residuals, from whatever source arising, is deferred till the appearance of another volume. A difference of 0·65 mag. from the mean has been selected as marking the limit of discordant measures.

It will be noticed that this photometric survey covers no inconsiderable portion of the area that has been examined by Kapteyn. The whole of the first volume of the Cape Durchmusterung, $-18°$ to $-37°$, is included, and should therefore furnish at once enlarged material for the examination of the systematic differences between photographic and visual magnitudes. Further, the meridian Pickering photometer is at present at the Arequipa Observatory, having been dismounted in September 1898, and the energetic Prof. Bailey is presumably using the same instrument at the southern station. Care has been taken to interchange the observers at Harvard so as to supply the means of reducing the observations on a uniform system, and thus continuing the Harvard survey to the Southern Pole. We may therefore look forward to the rapid acquisition of further data which will not only afford better values for the constants of reduction of the Cape plates, but exhibit in an unmistakable manner, though it may not solve, the perplexing difficulties to which we have alluded. Certainly, if energetic prosecution of the observations is of avail, the matter could not be in better hands than those of the Directors of Harvard and the Cape Observatories. W. E. P.

THE TREATMENT OF DISEASE BY LIGHT.

PHOTOTHERAPY, or the treatment of disease by light, has now, thanks to Prof. Finsen of Copenhagen, a recognised place in the domain of therapeutics. Finsen's first paper on the subject was published in 1893. In it he showed that the chemical or ultra-violet rays of the spectrum have a definite effect upon the course of small-pox, and he proposed that patients suffering from this disease should be kept in rooms from which the chemical rays of light were excluded by means of red curtains or red glass, in the same way that a photographer excludes these rays from his plates and paper. In an ordinary case of small-pox treated under the usual conditions, the eruption passes from the vesicular to the suppurative or pus-forming stage, and this condition is most marked upon the face and hands, the parts most exposed to light. It is in consequence of the destruction of the skin attendant upon the suppuration that the face and hands are so commonly the seat of hideous scars. Finsen's suggestion has been carried out with considerable success. In nearly every case in which the patient was kept in red light from the onset of the disease, there has been found to be a marked change in the course of the eruption. The suppuration and its attendant secondary fever have been almost, if not entirely, abolished, and as a result the patients recover with little, if any, scarring.

Finsen's next researches were made upon the action of light as an irritant, and they are of extreme interest to the biologist. It will suffice here to say that he found that the animal organism, especially in creatures which prefer to dwell in the dark, is markedly irritated by the chemical rays, while the other parts of the spectrum are non-irritant. From this he was led to investigate the effects of light upon bacteria. Here the field had already been occupied by Downes and Blunt, who, in 1878, in a paper read before the Royal Society, showed that the chemical rays are bactericidal. Duclaux, Arloing and others have worked upon the same lines and confirmed their results. It therefore seemed probable that superficial diseases of the skin caused by bacteria could be cured by the application of light. Of these, one of the most important and most intractable is lupus. Finsen, however, argued that the intensity of ordinary sunlight is obviously insufficient to kill the microbes as they lie in the skin, for lupus is particularly a disease of the face, which is more exposed to the sun than any other part. He therefore tried the effect of concentrating the light by means of lenses, cutting out the red and ultra-red rays by a blue medium. He found that cultures of micro-organisms *in vitro* were much more powerfully influenced by the concentrated rays. The sun's rays concentrated by the apparatus to be presently described were fifteen times stronger than ordinary sunlight. Powerful electric arc lights were also tried, and with a lamp of from 35 to 50 ampères the effect was similar to that of the sun, or even greater.

The next point to be determined was the penetrative power of light. For this purpose small sealed tubes containing silver salts were placed under the skin of animals and exposed to the concentrated light, and the silver was found to be blackened.

The effect of the blood circulating in the tissues was next demonstrated by a very ingenious experiment. A piece of photographic paper was placed behind the ear, and the outside of the lobule was exposed to the light. In about five minutes the paper was blackened. The experiment was then tried with the ear compressed between two pieces of glass so that it was rendered bloodless. The photographic paper was blackened by the light in twenty seconds. The absence of the red colouring matter of the blood allowed the chemical rays to penetrate with great ease.

The apparatus devised by Finsen for the treatment of lupus by the sun's rays (Fig. 1) consists of a large hollow planoconvex lens, filled with an ammoniacal solution of sulphate of copper and mounted upon a fork-like metal stand, so arranged that the lens can be moved about a horizontal and also round a vertical axis, and lowered and raised at will. The filtered sun's rays are focussed upon the area of skin to be treated, and at this spot is placed the compression apparatus. This is a very flat cylinder made of two plates of rock crystal fixed in a metal ring. Through the compression apparatus passes a current of cold water, so that the instrument is used to render the part to be treated bloodless and also to cool it. The pressure apparatus is held on the skin by a nurse throughout the whole sitting, which lasts one hour or a little more. The spot treated at each sitting is about the size of a sixpence.

The electric light apparatus (Fig. 2) is much larger and more complicated. Attached to a strong metal ring round a large arc lamp, of 30,000 to 35,000 candle-power, are four long cylinders like telescopes. Each telescope consists of two parts. The upper part, closed at each end by rock crystal lenses, makes the divergent rays of the arc light parallel, and the lower piece brings the rays thus rendered parallel, to a focus on the skin of the patient. The lower part of the apparatus is filled with distilled water and is surrounded with a jacket through which cold water circulates. The compression apparatus used for the sun treatment is placed, as before, at the focus of the light to render the skin bloodless and to keep it cool. The length of the sitting is one hour. There is no blue solution in the electric light apparatus as now made, as it has been found in practice that the tube of distilled water and the circulating water in the pressure glass are sufficient to absorb the comparatively small amount of heat-rays given off by the arc light. Rock crystal lenses are used because ordinary crown glass prevents a great part of the chemical rays from passing through.

FIG. 1.—The treatment by sun-light

As a result of an hour's application of the light the skin may be a little red, but there is no proper reaction for from six to twelve hours, when there is definite redness and swelling and sometimes slight blistering. In from three to seven days all trace of reaction has usually disappeared, and the skin, though still hyperæmic, can be treated again if necessary. The process is repeated over the whole of the diseased area and especially at its margins, the most active parts, until every sign of lupus tissue has disappeared. If the disease is extensive, the treatment lasts many months. It must be noted that in many of the bad cases not only is the skin affected, but also the mucous membranes lining the mouth and nose, and these parts can very rarely be influenced by the light.

In Copenhagen there is a Light Institute under the direction of Prof. Finsen, and a very large number of patients, more than 500, have passed through the institution. It was in Copenhagen that the Queen saw the treatment, and Her Majesty was so impressed with the good results attained there that she graciously presented a set of the apparatus to the London Hospital a little more than a year ago. The demands upon that institution became so great that a second and a third lamp had to be put up, and even with these it is impossible to cope with the influx of patients from all parts of the British Isles, and even from such distant colonies as Newfoundland and New Zealand.

The drawbacks to the treatment are, first, the length of time which a severe case takes, and, secondly, the cost. Not only is there the cost of the electric light and the necessary maintenance, but every patient has to be attended by a nurse. At the London Hospital it has been found that it costs about 400*l*. or more a year to run one lamp, so that the light department there necessitates an expenditure of 1200*l*. a year. It is, therefore, gratifying to find that Mr. Alfred Harmsworth has come forward and endowed one lamp by a munificent gift of 10,000*l*.

It must be noted also that public spirit in Manchester and Liverpool will shortly provide for the installation of the light treatment in these cities.

The results in cases of ordinary lupus are excellent, provided that the patients can remain continuously under treatment for a sufficient length of time. The average of a large number of cases is three months. Certain other diseases, lupus erythematosus, rodent ulcer and alopecia areata, are influenced favourably by the light treatment. In the first mentioned disease the results are not nearly so striking as in the common form of lupus, but about one-third of the cases do well.

The light treatment has been too recently tried in London for any definite statement to be made as to the permanence of the results. In Copenhagen it has been in use for five years, and some of the earliest cases are quite free from recurrence to date.

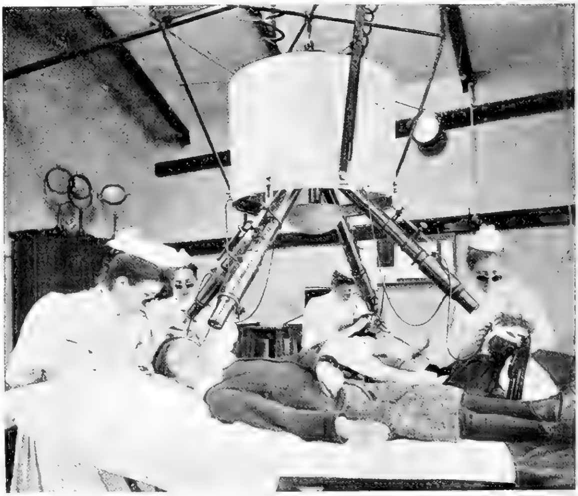

FIG. 2.—Treatment by electric light at the London Hospital.

The important advantages of this method of treatment over every other which has been used for lupus are that there is no destruction of tissue, there is no operation, and therefore no anæsthesia, for the treatment is pain-less, and, last but not least, in a disease which attacks the face the cosmetic results are wonderful. The skin of the areas treated is soft, supple and pale, and in some cases so nearly resembles the healthy skin that it requires careful observation to detect the difference. As we have already mentioned, the drawbacks are the time and the expense, and the impossibility of treating the mucous surfaces. If a cheaper method of application, with shorter exposures and the possibility of treating a larger area at one sitting, is introduced, there is no doubt that the light treatment will be used in every hospital where a suitable electrical installation is obtainable.

NOTES.

WE deeply regret to record that Prof. P. G. Tait, late professor of natural philosophy in Edinburgh University, died on Thursday last, July 4, at seventy years of age.

A STATUE of Chevreul is to be unveiled to-day at the Paris Museum of Natural History.

THE death is announced of Prof. T. H. Safford, professor of astronomy in Williams College, Williamstown, Mass., U.S.A. Prof. Safford was born in 1836 and was renowned for his mathematical attainments as well as for his work in preparing catalogues of stars.

THE death of Sir Cuthbert Peek, at the early age of forty-six, will be regretted in scientific circles, for he was a liberal patron of scientific work as well as an active worker. He was interested in many branches of science, being a Fellow of the Royal Astronomical, Geographical, Meteorological and other Societies, and of the Anthropological Institute. He also served on the councils of several scientific societies. He maintained a well-equipped observatory at Rousdon, near Lyme Regis, Devon, and the meteorological and astronomical observations made there have frequently been referred to in these columns. Science can ill afford to lose one who was in such complete sympathy with its interests.

TIDINGS have been received of the death of Dr. Joseph Le Conte, professor of geology and natural history in the University of California. He was born in Georgia on February 26, 1823, and was a son of Dr. Lewis Le Conte, the botanist. Having studied for the medical profession, and taken the degree of M D. at New York in 1845, he settled at Macon as a physician. Science, and particularly geology, however, attracted much of his attention. In 1856 he was appointed professor of chemistry and geology in South Carolina College, and he resigned this post in 1869 for the professorship at San Francisco. He was the author of a useful work on the "Elements of Geology" (1878), of which a revised edition was issued in 1889, and he gave special attention to the study of volcanic and also of glacial phenomena.

THE International Association for the Advancement of Science, Arts and Education will hold its second international meeting at Glasgow in the University and in the International Exhibition from July 29 to September 27.

THE *Times* correspondent at St. Petersburg states that the Imperial Geographical Society is sending an expedition to the Pamir under the leadership of Dr. Fedshenko with the object of making geological, botanical and zoological researches.

THE Institution of Mining and Metallurgy announce the intention to award two premiums of twenty-five guineas each for the best papers on the comparative merits of circular and rectangular shafts respectively, for mines of great depth. An annual prize of ten guineas will also be awarded for the best paper upon any subject connected with the treatment of ore. Particulars can be obtained from the secretary of the Institution, Broad-street House, London, E.C.

A CORRESPONDENT sends us the following translation of an article which appeared in the *Neue Freie Presse* of Vienna, and was translated in the Copenhagen Journal *Dannebrog* on June 28, upon the removal of Tycho Brahe's remains from his tomb. This is the first report we have seen of the event:—"On the occasion of the 300th anniversary of Tycho Brahe's death the Prague Town Council decided to gather together the remains of the celebrated astronomer, which were in the Teyn Church, and bury them anew. Under the guidance of Mr. Herlein this operation was commenced yesterday. After having lifted the stone block on the monument, which is situated near the first column in the nave and which bears a full-length effigy of the great astronomer, a semi-collapsed arch was found, and on removing the stones two mouldering coffins were seen. On the following day a committee met to determine whether these bodies were those of Tycho Brahe and his wife. Two workmen with candles descended into the vault and removed the débris which covered the coffins, the wood of which was quite rotten and fell to pieces at every rough touch. About 10 a.m. the lid of the first coffin was free to be removed. It was a surprising sight that met the eye; the body in the coffin was a wonderful likeness of the effigy on the monument. The head was slightly turned to one side, the bones of the face and the peaked Spanish beard being well preserved. The head was covered with a skull cap, and the neck was surrounded by a Spanish ruff which, like the remainder of the clothing, had suffered little during the 300 years since Tycho Brahe was laid in his last resting place. The feet were shod in long cavalry boots reaching up over the knee. That the body was Tycho Brahe's was also seen from the absence of the nose; Tycho lost this organ in a duel and wore a silver one in its place. Amongst the rubbish was found a silver wreath and spray of flowers. The construction of the grave was rather remarkable, the stones being laid loosely over one another. This is all the more astonishing seeing Tycho Brahe was buried with great pomp and honours, but it is supposed that the vault broke down during the restoration of the church in 1721."

DR. C. D. WALCOTT, director of the U.S. Geological Survey, contributes to *Science* of June 29 a long article on the relations of the national Government to higher education and research. The U.S. Congress has generously aided technical and higher education by grants of land to States and territories for educational purposes. This policy was inaugurated in 1787, when a contract was entered into between the Ohio Company and the Board of Treasury of the United States, whereby lot 16 in every township was given for the maintenance of public schools and not more than two complete townships were given perpetually for the purpose of a university, the land to be applied to the purpose by the legislature of the State. The most important act, after that of 1787, was that of 1862, granting land for the endowment of colleges for teaching agriculture and the mechanical arts. The total grants of land amount to about 20,000 square miles, about 4000 square miles of which are for the establishment of higher institutions of learning, and 16,000 square miles are in aid of "colleges for the benefit of agriculture and the mechanical arts." In addition, Congress now grants annually to each of the forty-five States the sum of 5000*l.*, which is expended under the direction of State boards. The policy of the U.S. Government has thus been to relegate the direct control of education to the States, aiding them in this work by grants of land, and in the case of technical education by grants of money also. The Government has carried on original research for its own purposes in the district of Columbia, through grants of money to its various scientific and technical bureaus. Of the total sum granted to these departments during the fiscal year 1901, more than 400,000*l.* or about 25 per cent. of the grant is available for scientific and research work and for higher education. The city of Washington possesses vast resources for work of this kind, and Congress has lately enacted that all the collections and museums in the city shall be available for higher education and research. The Washington Memorial Institution, which will begin work in three or four months, under the direction of Dr. Gilman, will suggest lines of investigation and coordinate the work that is being done by Government officials and private students.

As already announced, the British Congress on Tuberculosis will be opened at St. James's Hall on July 22. The Duke of Cambridge will inaugurate the congress on behalf of the King, who is patron. The work of the congress will be divided among four sections, viz.: (1) State and municipal—president, Sir Herbert Maxwell, F.R.S.; (2) medical, including climatology and sanitaria—president, Sir R. Douglas Powell; (3) pathology, including bacteriology—president, Prof. Sims Woodhead; (4) veterinary (tuberculosis in animals)—president, Sir George Brown. On Tuesday, July 23, the sections will begin their work, and at the second general meeting on the afternoon of this day Prof. R. Koch, of Berlin, will give an address. The chair will be taken by Lord Lister. On July 24, there will be, in the morning, a joint meeting of the medicine and pathology sections for a discussion on tuberculin. Prof. Brouardel, of Paris, will address the third general meeting in the afternoon. At this meeting Mr. Henry Chaplin, M.P., will be the chairman. The fourth general meeting, to be held on Thursday, July 25, will be addressed by Prof. McFadyean, of the Royal Veterinary College, and Lord Spencer will preside. The following are among the officers of the congress:—President of organising council, the Earl of Derby; chairman of organising council, Sir William Broadbent, F.R.S.; chairman of general purposes committee, Prof. Clifford Allbutt, F.R.S.; chairman of reception committee, Sir James Crichton-Browne, F.R.S.; hon. secretary-general, Mr. Malcolm Morris; hon. assistant secretary, Sir Arthur Trendell.

WE have received from the Deutsche Seewarte part x. of their colonial observations. This number contains a very valuable series of meteorological observations made in German East Africa, collected and discussed by Dr. Hans Maurer. Regular observations were begun there in 1891, but were not continuous owing to some unfortunate mishaps to the observers and to the difficulty of controlling the work at such a distance. Dr. Maurer was therefore dispatched by the German Government in 1895 to establish and superintend a network of stations, with the result that a very valuable series of hourly observations, from November 1895 to March 1899, have been obtained at several stations, and have been carefully collated and published in part i. of the work, including the harmonic constituents of the daily barometric oscillation for the monthly means. The second part of the present volume also contains some observations made before 1895 but not yet published, and a list of the works which contain observations previously published. The work is a most useful contribution to the climate of German East Africa.

IT has often been said that the study of electrochemistry is very much neglected in this country, and, indeed, until quite recently there was not, we think, to be found in any of our technical colleges a laboratory purposely designed for electrochemical and electrometallurgical work. Now, however, Owens College, Manchester, possesses in its new Physical Institute a laboratory thoroughly equipped for these purposes. Two rooms have been set apart for electrochemical work, the rooms chosen being in close proximity to the dynamo-room, from which currents up to 1000 amperes are obtainable. In addition to the ordinary equipment of a chemical laboratory leads have been run round the benches, so that every student has ready to his hand a supply of current at 2, 4, 6, 8 or 10 volts pressure. The apparatus requiring heavy currents, such as furnaces or large electrolytic tanks, is arranged on a bench at the end of the room at which the main leads from the dynamo-room enter. Bare copper wires are used for the conductors, the film of oxide and sulphide which forms on them protecting them sufficiently from too rapid corrosion. Now that Owens College has set so good an example, it is to be hoped that it will not be long before the other technical colleges recognise the need of efficient means of training students in this very important subject. Considering that a supply of cheap electric power is scarce, England may not be perhaps the most suitable country for electrochemical industries, but its backwardness in their development is undoubtedly aggravated by the lack of opportunity for young engineers to study the principles of electrochemistry and electrometallurgy.

NEWCASTLE-ON-TYNE may be congratulated on being the first place in the United Kingdom to see the inauguration of the practice of supplying electricity "in bulk." The large power station of the Newcastle-on-Tyne Electric Supply Co. was formally opened by Lord Kelvin on the 18th of last month, and the credit for the successful starting of the system must be shared jointly by this company and the Walker and Wallsend Union Gas Co. This latter company are taking a large supply from the Newcastle company and distributing it throughout the area under their control, which includes a number of big engineering and other works which require a supply of electricity for motive power or lighting. Many of these works make use of so much power that it has been found necessary to erect a separate substation in each case, power being supplied at high pressure to the substation and thence, after the pressure has been reduced, being distributed throughout the works. Supply is obtainable on either the continuous-current or three-phase systems. For the purpose of supplying the three-phase current, there are to be at the Neptune Bank station four 700 kw. sets generating at 5500 volts, and a 1500 kw. Parsons turbo-alternator. The continuous current is supplied by four 100 kw. dynamos generating at 240 volts; there is also a 150 kw. motor generator taking three-phase current at 5500 volts and generating continuous current at 240 volts, but designed so that it can be used in the opposite direction—that is to say, being driven by the continuous current and generating three-phase currents. A site has been obtained for the erection of another generating station in which to put up new machinery when the present station becomes fully loaded.

WE have received from the Meteorological Reporter to the Government of India a report on cloud observations and measurements in the plains of the North-Western Provinces of India during the period December 1898 to March 1900 (Indian Meteorological *Memoirs*, vol. xi. part iii.). The observations were taken and discussed under the superintendence of Mr. E. H. Hill; they include both the heights and movements, measured by means of two photogrammeters and a Fineman's nephoscope. In the fifteen months under review about 900 pairs of plates were exposed, and from these nearly 1000 calculations of heights of clouds have been made. The measurements have been arranged according to two seasons—June to October (the wet season, including the monsoon months) and November to May (the dry season). In the wet season the mean height of the cirrus was 35,000 feet, and the mean velocity 17·4 miles per hour; in the dry season 41,963 feet, and the mean velocity varied from 79 to 89 miles per hour. The mean height of the cumulus in the wet season was 5450 feet, and in the dry season (January and February only) 4100 feet, the velocities being respectively 13·7 and 10·2 miles per hour. The maximum velocity of the cirrus was estimated at 282 miles per hour both in February and March.

AN interesting letter by L. Schäfli on approximate integration is reproduced by Herr J. H. Graf in the *Berner Mittheilungen* for 1899, recently sent to us. The letter was written to a friend in explanation of certain difficulties he had experienced in reading Raabe's books on the calculus, and it probably dates from about 1840. It appears to throw some new light on the history of Bernouilli's numbers and functions, besides affording evidence of Schäfli's great power as a mathematician.

IN the *Journal de Physique* for May, M. Bernard Brunhes writes on the entropy of a gaseous mixture in combustion. It has been hitherto regarded as an objection to the use of entropy diagrams that they could not be used in connection with gas and oil engines, on account of the essentially irreversible nature of the explosions and the consequent uncertainty as to whether the entropy of the mixture was calculable or could even be said to exist. M. Brunhes now shows that, under certain well-defined conditions, the entropy is both determinate and calculable.

PROF. ORESTE MURANI points out in the Lombardy *Rendiconti* that a focus-tube at a certain degree of vacuum acts like an "electric valve" for alternating currents, in that it allows the current to pass in one direction but not in the other. The notion of an electric valve appears to have been originally due to Gaugain, and it has been known that a Geissler's tube in which the electrodes have different forms may act in this way. In the case of a focus-tube there appears to be a superior and an inferior limit to the degree of exhaustion at which it acts in this manner, the superior limit corresponding to a pressure of about 0·1 mm. of mercury, and the inferior limit, which has not been determined with such certainty, corresponding to 0·07 mm. Prof. Murani considers that a focus-tube may be used to indicate the sense of a discharge in certain cases where a more direct method is inapplicable; it might be also used to convert an alternating current into a direct one, but the intensity of the latter would be very small.

THE monaural localisation of sound receives treatment at the hands of Prof. James Rowland Angell and Dr. Warner Fite in the *Psychological Review* for May. The paper reports a series of observations on the capacities of auditory localisation in a person entirely deaf in one ear, but parallel observations have in certain cases been made upon a person of normal hearing. So far as it is possible to briefly give some idea of the conclusions, it is shown firstly that the differences in the localising capacity for complex sounds in binaural and monaural hearing are, so far as concerns these subjects, interpretable as chiefly differences in the magnitude of the difference limen for locality rather than as absolute differences in the kind of localising process involved. The experiments amply sustain the introspection of the subject in pointing to qualitative differences in the sounds coming from different directions as the basis of the localisations. Such qualitative differences may be due to the damping or reinforcing of certain partial tones by the organs of the ear and the head, and it is noteworthy that generally sure tones are unlocalisable in monaural hearing. The presence of eye-reflexes was often very marked, and the final localisation was frequently made on the basis of a seeming correspondence between the eye-strains and the supposed direction of the sound. This statement, however, leaves untouched the physiological basis of the eye-movements. Finally, there is no good evidence for supposing that cutaneous sensations play any part in the localisations.

THE thermal conductivity of the living human skin forms the subject of an investigation by Mr. J. Lefèvre in the *Journal de Physique* for June. Regarding the skin as a wall about 2 mm. thick, three coefficients have to be found, namely, the surface conductivity, the true conductivity through the substance forming the skin, and the internal surface conductivity between the skin and the adjoining tissues. To find these it was necessary to determine the rate of flow of heat across a unit area of the skin, and to measure the distribution of temperature from the surface downwards. For the former purpose M. Lefèvre immersed himself in a bath of water which served as a calorimeter, for the second he used thermoelectric elements, that used for subcutaneous observations taking the form of a fine needle. The experiments show that the skin is a bad conductor, its true conductivity being about the same as that of wood, of the same order as that of gutta percha, about 5 or 6 times that of wool and 750 times that of air. The conductivity is only half as great at 5° as at 30° C. The exterior surface-conductivity of the skin in contact with water appears to be approximately independent of the temperature, but the coefficient across the surface separating the skin from the adjoining tissues increases considerably as the temperature falls from 30° to 5°, and the latter increase more than counterbalances the decrease in the true conductivity, so that the loss of heat at 5° C. is twice or thrice as great as it would be according to Newton's law.

THE new number of the *Mittheilungen* of the Vienna Geographical Society contains two papers of interest. Herr H. Anschutz-Kaempfe describes a plan for exploring the Arctic Ocean and reaching the North Pole by means of a submarine vessel. Herr V. von Loziński treats of chemical denudation in relation to geological time, and gives a valuable summary of recent work bearing on this subject. The calculations of Mr. Mellard Reade and von Romer are specially dealt with, and the latter are repeated, with modifications, employing the most recent data of Murray, Gümbel and others.

DR. G. SCHOTT gives, in the *Verhandlungen der Gesellschaft für Erdkunde zu Berlin*, an interesting forecast of some of the oceanographical results of the *Valdivia* Expedition, the full report on which may be expected next winter. The *Valdivia* observations have been combined with older material so as to bring maps of distribution of temperature, as far as possible, up to date, and from these Dr. Schott draws some important general conclusions. In the open ocean three temperature layers are recognised—a surface layer, 0 to 100 metres, in which the distribution is chiefly controlled by horizontal movements; a middle layer, 150 to 800 metres, controlled by vertical movements; and a bottom layer, beyond 1000 metres, in which horizontal movements are again specially important. A "Sprungschicht" occurs in every ocean, its mean depth being 25 to 80 metres in the Atlantic, 90 to 140 metres in the Indian, and 110 to 180 metres in the Pacific Ocean.

THE "Karlseisfeld" was first visited by Friedrich Simony in 1840, and since that date almost every change in the glacier has been carefully observed. Simony made his last photographic survey in 1890, and since his death a survey was made, in 1896, by von Groller. The retreat of the glacier during the five years following made another survey important, and this was accordingly carried out by Freiherr von Hübl. The results are published in the *Abhandlungen* of the Vienna Geographical Society, and, apart from their value as a study of the glacier, they form a model example of the application of modern methods of photographic surveying to work of the kind. The account of the survey forms the first of three parts of a report to be published under the editorship of Herr August von Böhm; the second part is to deal with the history of the glacier, and the third with its present development. In the same number of the

Abhandlungen Dr. Johan Cvijić publishes the second part of his morphological and glacial studies in Bosnia, Herzegovina and Montenegro, dealing with the *Karstpoljen* of Herzegovina and West Bosnia.

IN the *Transactions* of the Edinburgh Geological Society (vol. viii. part i. 1901) Dr. W. Mackie publishes some chemical analyses of Scottish sands and sandstones ranging in age from the Torridon Sandstone to the Blown Sands of Culbin. These analyses show that the proportions of the total alkalis follow fairly closely the results obtained from the proportions of fresh felspar in the several formations. Thus the Torridon Sandstone, an arkose, which contains fresh felspars, gave an average of 4·61 per cent. of alkali, chiefly potash. Soda is hardly represented. Hence the author doubts if such sandstone could be converted by metamorphism into a gneiss as has been suggested. The bearing of his analyses on similar questions is discussed, and he concludes (1) that a silica percentage over 78, an alumina percentage under 11, and a low percentage of lime and of total alkalis, especially of soda relatively to potash, indicate a sedimentary origin of metamorphic rocks; and (2) that a silica percentage not above 78, an alumina percentage not under 11, a high percentage of total alkalis, &c., indicate origin from an igneous rock. Mr. H. M. Cadell contributes to the same *Transactions* an important article on the geology of the Oil Shalefields of the Lothians; and Mr. Herbert Kynaston draws attention to the effects of contact metamorphism round the Cheviot granite.

THE second number of vol. ii. of the *West Indian Bulletin* has just been issued by the Imperial Agricultural Department. It is devoted wholly to a continuation of the full reports of the papers and discussions at the Agricultural Conference held at Barbados in January last. A great deal of the most useful information is brought together in these pages, the subjects dealt with being of a varied character, and not in all cases strictly agricultural. Dr. Alford Nicholls deals with the difficult question of bush fires, which he divides into five classes, approving of some, condemning others. Mr. Watts treats of soils in "orchard" cultivation, and of pine-apple cultivation in Antigua; Mr. Hart of rubber planting in the islands (illustrated); Mr. Sands of the cultivation of onions in Antigua; Mr. Meaden of breeding for beef in Trinidad, and, with Mr. Hart, of zebu cattle in the same island; and Mr. Whitfield Smith of artificial drying of cacao. Dr. Duerden's instructive communication on the marine resources of the British West Indies, which was some time ago issued as an extra number of the *Bulletin*, is reproduced *in extenso*.

THE afforestation of Ireland is advocated by Dr. R. T. Cooper in the *Irish Times* as a means of increasing the value and productiveness of the country. In Ireland there are about five million acres of unproductive land in a total acreage of 20,808,271, every square yard of which could be improved and fertilised by tree cultivation. Yet in all Ireland during the year ending June 1900 only 629 acres were planted with trees, while 1451 acres were cleared of timber. A serious attempt ought to be made to prevent this destruction of forest and recover the immense areas of "bog waste and mountain land" by a scientific distribution of trees.

AN interesting illustration of the practical importance of the recent discovery that leguminous plants possess the power of utilising the free nitrogen of the atmosphere, and thus increasing the nitrogenous constituents of the soil, is furnished by a pamphlet on shade in coffee culture, by Mr. O. F. Cook, being *Bulletin* No. 25 of the U.S. Department of Agriculture (Division of Botany). It seems that coffee growers in Central America, Venezuela and Columbia advocate a certain amount of shade for the coffee plantations, while those in Brazil and the East Indies do not. Mr. Cook suggests that the explanation of these contrary results lies in the fact that, while in the first-named countries the shade plants employed are almost exclusively leguminous trees and shrubs, in the latter they are chiefly figs, bananas and other non-leguminous plants. Hence the problem is one rather of nutrition than of insolation. A long list is given of the shade plants employed by coffee growers, and the pamphlet is illustrated by a number of photographs.

PROF. F. PLATEAU, of Ghent, has recently published several fresh papers, in the *Annales de la Société Entomologique de Belgique* and the *Mémoires de la Société Zoologique de France*, on the sources of attraction in flowers for insects. His previous conclusion, that insects are but little attracted by bright colours, was confirmed by experiments which showed that brightly coloured stuffs and scintillating metallic objects placed among the leaves had but little attractiveness for insects. With regard to the constancy of insects in visiting the same species of flower only on the same flight, he states that species of Bombus are very inconstant; *Apis mellifica* and *Anthidium manicatum* are, on the other hand, remarkably constant; species of Megachile and Coelioxys less so. The habit of constancy is attributed to a desire on the part of the insect for a saving of labour. The Syrphidæ (hover-flies) show a considerable tendency to be attracted by bright colours, whether of flowers or of inanimate objects. To this quality, and not to any æsthetic sense, is to be attributed their habit of hovering over flowers.

A WELL illustrated article by Prof. W. M. Wheeler, bearing the title of "Impostors among Animals," presents to the readers of the July number of *The Century Magazine* some of the leading facts connected with the "mimicry" of animate and inanimate objects by animals, and the consequent adaptation of the latter to their surroundings, in a pleasant and attractive manner. The first illustration shows the marvellous resemblance presented by certain bugs to the rugged bark of the stem on which they dwell, while the second displays the mimicry of orchids by various members of the Orthoptera, which assume a stationary posture with outspread wings on such occasions. Attention is specially drawn to the circumstance that while protectively coloured animals have, as a rule, a simple coloration and quiescent habits—frequently accompanied by the "death-feigning instinct"—those which depend for safety on "warning colours" present the very opposite conditions, being brilliantly and often gaudily coloured, while their habits are calculated to provoke attention and attract observation.

THE current number (vol. lxx. part iii., No. 1) of the *Journal* of the Asiatic Society of Bengal contains several interesting papers on folk customs in India. Captain W. Haig records the origin, the marriage laws, religious observances and funeral rites of the Rangari caste in Barar; in another paper he does the same for the Velama caste, and in a third communication he narrates the legendary account of Shah Abdur-r-Rahman-i-Ghazi, the warrior saint of Barar. Mr. S. Appadorai gives far too brief a paper on the heroic Godlings in Malabar folklore; and the riddles current in Bihar are recorded by Mr. S. C. Mitra. In a very interesting paper, illustrated by four plates, the Rev. P. O. Bodding describes a number of polished stone implements found in the Santal Parganas. These, as almost everywhere else, are believed to be thunderbolts. The Santals believe that a house where such a "thunderbolt" is kept is proof against lightning, and, as in the north of Ireland and elsewhere, they are also supposed to possess remarkable therapeutic power. Water in which a thunderbolt has been rubbed or placed is used, both externally and internally, to cure many ailments.

THE optical establishment of C. P. Goerz, at Friedenau, Berlin, has just produced its 100,000th lens—a Goerz double anastigmat. To have placed upon the photographic market 100,000 anastigmat lenses in eight years (since 1893) is a noteworthy record.

M. MORENA Y ANDA publishes in the *Transactions* of the "Antonio Alzate" Society of Mexico a table showing the diurnal variability of air temperature at Tacubaya for each month of the fifteen years 1884–1898. The hours of observation are 7 a.m., 2 p.m. and 9 p.m.

DR. MAX VERWORN'S "Allgemeine Physiologie" was welcomed as a valuable work when it appeared in 1894, and its scope and character were described in these columns (vol. li., p. 529). The work has been translated into English, French, Russian and Italian, and has taken its place as a standard textbook of general physiology. The third edition has now been published by Herr Gustav Fischer, of Jena.

THE syndics of the Cambridge University Press have undertaken the publication of a work on the fauna and geography of the Maldive and Laccadive Archipelagoes. An expedition, consisting of Mr. J. Stanley Gardiner, Mr. L. A. Borradaile and Mr. C. Forster Cooper, passed eleven months in these two groups, and the work will contain the scientific results of the visit. The chief object of the expedition was to investigate the interdependence of the physical and biological factors in the formation of atolls and reefs. To this end upwards of 300 dredgings were taken, a large number of soundings were run, and every group of organisms was carefully collected. The land fauna was carefully and exhaustively collected, and, being from an undoubted oceanic area, cannot fail to be of interest. The marine collections fill in an almost unknown gap between the Red Sea and the East Indies, and are the most extensive ever obtained from any coral, oceanic area. The work will be published in eight parts, of which the first will appear in October next.

IN the last *Berichte*, Nencki and Marchlewski describe the very interesting discovery of the close chemical relationship existing between the red colouring matter of the blood and the green chlorophyll of plants. Hæmatoporphyrin a derivative of hæmoglobin, and phyllocyanin obtained from chlorophyll, both yield on reduction hæmopyrrol, which is probably an isobutyl or methyl propyl pyrrol.

IN the newly issued *Bulletin International de l'Académie des Sciences de Cracovie*, L. Bruner publishes the results of his dynamic investigations on the bromination of aromatic compounds. The dependence of the velocity of bromination on the nature and position of the substituting groups in the benzene ring has been studied, and especially the catalytic activity of the most important bromine "carriers." In respect of this capacity, aluminium, chromium, iron and thallium salts, compounds of antimony and phosphorus, and finally iodine have been investigated. It is found that the catalytic activity of the bromine "carriers" depends upon the nature of the substance which is being brominated, so that the arrangement of these bodies in a general series according to their activity is not possible. For benzene and bromobenzene the order is (1) aluminium, (2) thallium, (3) iron salts, (4) iodine, (5) antimony, (6) phosphorus halogens.

THE additions to the Zoological Society's Gardens during the past week include two Green Monkeys (*Cercopithecus callitrichus*) from West Africa, presented respectively by Mr. R. de Courcy Hickton and Mr. S. Prust; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. Mould; a Crab-eating Raccoon (*Procyon cancrivorus*) from South America, presented by Mr. B. W. Gardom; a Cuckoo (*Cuculus canorus*), British, presented by Lieut.-Colonel J. S. Benyon; an Alligator (*Alligator mississippiensis*) from North America, presented by Mr. W. Phillips; two Mocassin Snakes (*Tropidonotus fasciatus*) from North America, presented by Captain J. B. Gilliat; a Great Wallaroo (*Macropus robustus*), four Bridled Wallabies (*Onychogale frenata*) from Australia, two Parrot Finches (*Erythrura psittacea*) from New Caledonia, two Grey-headed Porphyrios (*Porphyrio poliocephalus*), two Ceylonese Terrapins (*Nicoria trijuga*) from India, five Derbian Sternotheres (*Sternothaerus derbianus*) from West Africa, two Grey Monitors (*Varanus griseus*) from North Africa, deposited; two Griffon Vultures (*Gyps fulvus*), European, received in exchange; a Wapiti Deer (*Cervus canadensis*), three Glossy Ibises (*Plegadis falcinellus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

LIGHT VARIATION OF THE MINOR PLANET (345) TERCIDINA.—In the *Astronomische Nachrichten* (Bd. 156, No. 3726), Herr J. Hartmann gives an account of his investigations of the variation in brightness of this small planet, first pointed out by Prof. Max Wolf, of Heidelberg, in 1899 (*Astronomische Nachrichten*, No. 3704). Two photographs were obtained on April 20 and a third on April 22, all with the large Potsdam refractor. Reproductions are given showing the trails of the planet with reference to the neighbouring stars. The period deduced is as follows:—

Beginning of increase ...	9h. 0m.		
Culmination	10h. 14m.	4h. 10m. = 250m.	
End of increase	13h. 10m.		

In the same journal Prof. Max Wolf gives a reproduction of a photograph taken with a 6-inch Voigtlander objective on April 22, the period determined from this being about 240m., which is in close agreement with that determined from the Potsdam photographs. The value determined from the older observations on 1899 November 4 was 290 minutes.

UNITED STATES NAVAL OBSERVATORY.—The recent issue of vol. i. of the second series of *Publications* of the U.S. Naval Observatory contains the first results of work done at the institution since the removal from the old site and the remounting of the instruments at the new observatory. In this volume a new method of publication is initiated, the observations made with one instrument and extending over several years being given together instead of all observations being published annually. This first volume contains the reduced observations of the sun, moon, planets and many miscellaneous stars made with the 9-inch and 6-inch transit circles during the years 1894–1899.

THE COMPTOMETER.[1]

IN acceding to the editor's request to contribute an article to NATURE upon this instrument, I should like at the outset to express the feeling of curiosity with which any one, familiar with the many arithmometers now so generally in use, must introduce himself to the examination of the comptometer. He will probably know before he begins that it is a mere adding machine; that whereas any arithmometer at each turn of the handle adds or subtracts, as the case may be, any figure set upon the machine, no matter how many digits within the capacity of the machine there may be, or how many times, or how fast within the capacity of the operator he may turn the handle, so that by means of the shifting result-slide multiplication and division can be performed at a rate, and without mental effort, that is a tax upon our imagination, the comptometer is a mere adding machine in which the operator acts upon one key at a time, which adds, each time he presses it, the number on its head to the corresponding digit on the register below. While, therefore, the machine is evidently well adapted for addition, which is so simple an operation that most people believe an instrument for the purpose is not worth the expense of purchasing, it would appear at first that the process of multiplying, to be explained shortly,

[1] Chicago, U.S.A.: Felt and Tarrant Manufacturing Co. Manchester: The Calculating Machine Co.

must be so cumbersome as to leave the comptometer far behind the more automatic arithmometers and so little better than head and pencil work as to be a gain of doubtful value.

When, further, he finds out that the inventor has evaded one of the principal difficulties of arithmometer design, which relates to the carrying of the tens, but which is due to the provision that this operation must occupy the second half of the turn of the handle and must, even then, be successive all down the row so as to allow of the nearly simultaneous and overlapping operations on all the digits, in the comptometer it is not possible where carryings come in to depress two keys simultaneously, for in that case the carrying will fail. On the other hand, if the keys are operated singly as many carryings as are necessary will be accomplished.

When, again, the arithmometrician, if I may so designate one familiar with the use of the arithmometer, finds that the comptometer, like the Income Tax man, can never subtract anything (it can only add, and so apparently can never divide) his despair is likely to be complete and he might well condemn the machine as a toy.

I will not go so far as to say that this exactly represented my feeling when I began to prepare this notice, for I had known the construction of the instrument for some years and was generally familiar with it. However, I did feel that, from a mechanician's point of view, it represented a retrograde step, and it was only the knowledge that the comptometer was extensively used in the United States, where appreciation of time-saving appliances is more developed than here, that made me feel that the comptometer must have advantages perhaps more than sufficient to compensate for its operative deficiencies.

The comptometer is a neat-looking instrument cased in mahogany, occupying $14\frac{1}{2} \times 7\frac{1}{2}$ inches on the table, and it is four inches deep. On the upper surface there are, in the eight-column machine, eight columns of spring-actuated number keys, nine keys to each column. The lowest key of each column, or rather the one nearest the operator, is marked in black 1, and these are called the 1 row, the next 2, and so on up to 9. All the even keys are flat and the uneven concave, so the operator knows at once, without looking, if his finger has got one row too high or too low. At the end next the operator is a row of nine number wheels, or one more than the number of columns, on one axle, seen through windows, so that only one figure on each can be read. This is called the register. The axle terminates outside on the right in a milled head, and below this there is a liberator handle. If the operator finds any figures on the result wheels that he does not want he presses the liberator handle with one finger and begins to turn the milled head. He then turns this as far as it will go, when nine 0's will appear on the number wheels. The machine is now ready to begin. If any key is pressed down the figure shown in black on that key will immediately appear on the corresponding number wheel below. If it or any other key in the same column is pressed, the figure on it will at once be added to the figure already on the number wheel. If the result is more than 9, 1 will be carried to the next number wheel to the left. If that should happen to be already 9, one will be carried on again and it will become 0. If all the figures are 9 and 1 is added to any one, then it and all to the left will immediately become 0. The action is almost instantaneous, but not quite, as each number wheel on becoming 9 leaves a trap set which it lets off on becoming 0. The trap then adds 1 to the next number wheel to the left. If this is 9 the same thing happens again, and so on across the machine as far as 9's happen to extend; so the action is really successive and the wave of motion can just be detected if it is looked for.

Any key instantly returns to its place under the action of a spring when the finger is removed. The necessary movement of the 1 keys is $\frac{1}{4}$ inch, while for the 9 keys $\frac{5}{8}$ inch is required with intermediate movement for intermediate figures. The pressure required is moderate, but more than is necessary for a typewriter. The rate of striking the keys may become, with practice, very great, so that, though numerous strokes are required in a multiplication, the result may nevertheless be found very quickly. Judging by the time that is stated to be necessary for working certain examples, a rate of six or seven strokes a second is certainly attainable, in fact, with but little practice I find this to be possible and that the machine works correctly at this rate.

The question will naturally arise here whether there is any fear of overshooting by the wheels of the register, as they are clearly set into very rapid rotation and have to be suddenly and exactly stopped. Various methods of stopping number wheels are in use in arithmometers—spring clicks, cams like the Geneva stop in clockwork, and a mere brake; the method used here is more direct and positive than any of these, for the key at the end of its depression operates a long light lever which brings a rigid stop between two pins on the number wheel of the register, locking it absolutely and ensuring its stopping in the correct position. The driving forward of the number wheels by the keys is effected by a series of long light levers, each operated by any one of the keys of one column. The 9 key is near the fulcrum end, while the 1 key is near the number wheel end and the others are in intermediate positions. A toothed arc at the end of each lever gears with a corresponding pinion on the common axis of the number wheels, and each of these pinions drives round its number wheel by a ratchet and pawl. Each number wheel in moving from 0 to 9 raises a light lever by means of a cam to its highest position, which it lets drop on completing its turn to 0 again. The lever in its descent moves on the next wheel to the left one tooth. If, therefore, the key of that wheel is being depressed at the same time, the carrying trap will not move it an extra tooth, but will merely join with its operating lever in moving it through one unit of movement, and the carrying will be lost.

To the left of each 1 key is a little push, which may be pressed with one finger when any key in that column is being depressed. This push throws the carrying trap out of gear with the next number wheel, so that no carrying can take place. This enables the operator to alter any figure in the result, or to bring it to 0 by adding to it the necessary number without, at the same time, changing any other figure to the left. They are also used in some special operations.

I have now probably written enough to enable any one interested in these machines to understand what the comptometer is like and also its mode of operation. The next thing is to explain how a machine that can only add, and only do that one figure at a time, may nevertheless be used for performing all the ordinary arithmetical operations, such as any arithmometer will perform.

Addition needs no more explanation. The speed merely depends on the rate at which an operator can read the columns of figures and get his fingers on to the right keys. A mere dab at the key such as is desirable with a typewriter is not appropriate here, as the key must be pressed right down to its stop, otherwise it may add a number less than that printed in black upon its head. To acquire the proper stroke, high speed and certainty of getting on to the right keys evidently requires practice; it would be interesting to see a really skilled operator at work.

In most arithmometers subtraction is effected (this is most generally wanted for the purpose of division) by turning the number wheels in the reverse direction, when the carrying acts in the reverse direction also. It is merely addition backwards. There is, however, a method of in effect subtracting on a machine which, like the comptometer, does not admit of backward motion. It is to add the arithmetical complement. This, for instance, has been used in some operations in Mr. Edmondson's circular machine. If you wish to subtract, say, 7, you have merely to add 3 and prevent the machine from carrying with the push. If you wish to subtract, say, 29, you have merely to add 71 and prevent the second figure from carrying. Similarly, to subtract, say, 23456789, it is merely necessary to add 76543211, each digit to be added being 9 – the one to be subtracted except the last operative digit, which must be 10 – the one to be subtracted, or 1 more than in the case of the others. If the arithmetrical complement had to be found by the operator the machine would not be of much use, but it has not. Every key has a smaller figure in red upon it, which is 9 – the black figure on the key. All that is necessary, therefore, in subtraction is to work with the red figures, bearing in mind only that the last operative figure to the right must be taken on the next key above, and that the push belonging to the last figure on the left must also be used to prevent carrying improperly.

Multiplication of any number by another of one digit is, of course, simple enough. To multiply, for instance, 37921 by 7 the series of keys corresponding to the number 37921 are each struck seven times, or else working on the 7 row the key farthest to the right is struck once, the next to the left twice, the next nine times, and so on. Either operation will produce the right answer, but the second one is preferable because, having put the finger on the last key of the seven row, there is no more occasion to look at the machine; the eyes can be kept on the paper and the series of keys struck the proper number of blows. There is no fear of sliding off on to the next row, as the change from the concave to the level keyheads would at once be felt.

If the multiplier has more than one digit the second method is still more to be followed. Take, for instance, an example illustrated in one of the pamphlets of the company, 2253×84. You do not, of course, strike the 2, 2, 5 and 3 keys 84 times or the 8 and the 4 keys 2253 times, though if you did the right answer would be found. You get on to the 4 row and strike the last key to the right three times, the next five times and the next two twice each. Then you get on to the 8 row and, starting at the last key but one to the right, you do the same again. The total number of strokes necessary may be found by adding together the digits in one factor and multiplying the sum by the number of digits in the other. In this case $12 \times 2 = 24$ strokes. That at, say, 6 strokes a second will be four seconds for the operation. Then the result has to be read and the result wiped off ready for the next. With a greater number of digits the operation is the same.

It constantly happens in extended calculations that the result upon the number wheels has to be further operated upon. If the next operation is one of addition or subtraction, the previous result is in the proper place; the same is true if it is to be divided. But if it has to be multiplied by a new number, the natural thing is to copy it down, wipe it off the machine and multiply in the usual way. This necessity, or supposed necessity, was overcome in Mr. Edmondson's machine by the ingenious method of "working off" results from the machine as distinguished from the usual way of working results on to the machine. That process is impossible in the comptometer, as it is in every other machine except Edmondson's, but instructions are given for a method of multiplying by a figure already on the register without the necessity of wiping it out, which is equally applicable to all arithmometers. It is simply to leave it there and multiply the other factor by a number which is one less than the right one. Then, as the new product by $n-1$ is added to that by one already there, the result is what is wanted. By beginning at the left hand side instead of the right, as explained in the directions, which are abundantly clear, each new figure to be used is read from the undisturbed number wheel most to the left, so that there is no necessity to write down the intermediate result. Also, in multiplying long decimals it is best to begin at the left, as in that case a sufficient number of figures can be found on the machine, those discarded having no meaning if the figures operated upon are the results of observations and are not absolute figures.

Division can, of course, be effected if subtraction can be, for it is merely necessary to go on subtracting the divisor from the earlier digits of the quotient until what is left in those places is less than the divisor, then to shift the place one to the right and start subtracting again. The number of times the subtraction is effected at each place is the figure of the quotient at that place. This, after all, is what every arithmometer does, and the series of indices which record the number of turns of the handle in each place enable the operator to read off the quotient when he has gone as far as may be necessary.

Now in the comptometer these counting wheels, or their equivalent, are absent, and so, unlike arithmometers, it does not leave a record of a multiplication actually effected, but only of the result. If, therefore, a wrong key has been struck, except that the result is wrong there is no means of finding it out, whereas in an arithmometer it is usual to compare the setting and the record of the counting wheels with the figures given, to be sure that the actual operation given to the machine was that intended. If any one or more of the counters indicates a wrong figure it is merely necessary to put that place into operation and make so many turns of the handle with the + or − gear, or forwards or backwards, as the case may be, to make the counter read the intended number, when the result will also become right.

In the comptometer these counters are absent, and there is no kind of record in a multiplication or addition except the result of what the operator really gave to the machine. It would therefore appear that in division there can be no record of what was done, and, therefore, that it would be necessary to write down figure at a time the number of times the set of keys were struck in each place. It is just here that a pleasant surprise is met with, and a property of the method of subtracting, by adding the arithmetical complement, is available which I do not think would be foreseen by the arithmometrician in general.

The property is this. If the arithmetical complement is added to the group of digits to the left of the dividend that would be first used in ordinary division, and if the push is not put into operation to prevent the carrying, then when the addition has been effected the right number of times the digit on the result wheels which has received these carryings will itself be the same as the number of additions, and the figures to the right of it will have become less than the divisor. All the operator has to do, therefore, is to watch this wheel and count 1, 2, 3, &c., every time he strikes the proper keys; when this wheel reads the same number as his count he then looks at the figures to the right; if they are more than the divisor he goes on striking and counting until they are less. The counting here is not necessary, but it is safe. As soon as they are less the wheel receiving the carryings records the corresponding figure of the quotient, the same number, in fact, that he will have counted.

This operation is best explained by the aid of an example. Divide 365 by 52. 365 is first set on the result wheels as far to the left as possible. Then the keys carrying the red numbers 5 and 1 in the columns over 6 and 5 are struck, while the operator watches the wheel at first showing 3 and counts 1 for each time he strikes the 5 and 1 keys. These really add 48 each time.

The series of numbers indicated below will then one by one appear:—

	365
Count 1	413
,, 2	461
,, 3	509
,, 4	557
,, 5	605
,, 6	653
,, 7	701
